

Debt Indexation and the Fiscal Theory of the Price Level*

Tobias Kawalec[†]

March 21, 2025

Abstract

In this paper, we analyze the importance of *inflation-indexation* of a part of the stock of government debt. We establish empirically using both Local Projections and a narratively identified specific fiscal shock that sovereign deficit shocks are more inflationary when the share of government-issued inflation-indexed debt is higher. We leverage this finding to introduce inflation-indexed debt in macroeconomic models focusing on interactions of fiscal and monetary policy through policy rules, where we show that: (i) even absent further frictions, inflation-indexed debt makes the price level backward-looking (i.e., it becomes a jump-state variable), (ii) it tightens bounds that pin down ‘active fiscal policy’, (iii) it allows us to discriminate to some degree between ‘fiscally-led’ mechanisms and ‘HANK-type’ mechanisms surpassing Ricardian equivalence, and (iv) in a calibrated HANK model, a one percentage point increase in the share of inflation-indexed debt in overall government debt increases the volatility of the response of inflation to government spending by 3% relative to a no-indexed debt baseline case in a world of fiscal dominance, while there is no sizable effect under monetary dominance.

Keywords: Debt Indexation, Government Debt, Fiscal-Monetary Interactions.

JEL Codes: E52, E63, H63

1 Introduction

This paper aims to shed light on the role that inflation-indexed debt plays in magnifying inflation in response to changes to the surpluses raised by governments. It should be immediate that if the government budget balance indeed plays a crucial role in determining the price level, then an interesting feedback loop may arise if the face value of a part of that debt *itself* changes either with the price level or its rate of change. We motivate this idea by using data on a specific narrative fiscal shock that we track through market expectations on sovereign deficits and government bond price revaluations, showing a sizable fiscal inflation multiplier related to the share of inflation-indexed debt. Our second empirical finding, based on an exercise with local projections using exogenously identified shocks that increase fiscal deficits, reflects that inflation-indexed debt indeed appears to boost ex-post inflation outcomes in response to such shocks.

We next move on to introducing inflation-indexed debt in a one-equation model of government debt-driven price level evaluation. In that model, we establish that the price level becomes a state variable without further ado: previous price levels matter for the determination of the current price level when inflation-indexed debt is present, even without further sources of stickiness being present in the economy. For such an economy with inflation-indexed debt, we are able to prove uniqueness of the stationary equilibrium in a corresponding dynamic general equilibrium economy.

This paper therefore also adds to recent debates about determinacy properties of non-Ricardian economies with FTPL-type mechanisms. Farmer and Zabczyk (2019), Hagedorn (2021, 2024), argue that such models cannot yield unique equilibrium outcomes when the real interest rate is itself an equilibrium object, while Angeletos et al. (2024) question the sense of the underlying equilibrium selection mechanism. We leverage our findings related to inflation-indexed debt to set their contributions in the wider context of nominal equilibrium determination, finding additional conditions that pin down unique rationalizable equilibria.

Finally, we analyze the combined effects of household heterogeneity and the presence of inflation-indexed debt to monetary and fiscal spending shocks in a full heterogeneous-agent New Keynesian (HANK) model à la Kaplan et al. (2018), making use of the methods pioneered in Auclert et al. (2021) to solve heterogeneous-agent models up to first-order in aggregate variables, while preserving heterogeneity with respect to the individual agents in this economy.¹ Here, inflation-indexed debt matters quantitatively by increasing the volatility of inflation by roughly 3% for each one percentage point increase of the share of indexed debt in the overall debt portfolio. We furthermore establish that the classic notions of ‘active/passive monetary/fiscal policy’, as derived by Leeper (1991), do not directly translate into the world with inflation-indexed debt, even though similarities in the determination of equilibria prevail.

Figure 1: The share of inflation-indexed debt in the total sovereign debt portfolio and its average weighted maturity over time. The UK is marked orange, while grey lines and bars indicate other BIS member countries. Data source: BIS (2024).

¹Crucially, this allows us to preserve non-linear risk aversion motives for holding indexed debt, as indexed debt will be the principal insurance device of households against inflationary shocks.

To establish the relevance of our idea behind introducing indexed debt, figure 1 shows both the share of inflation-indexed debt as part of the overall debt stock and its maturity over time. While there is considerable heterogeneity across countries, indexed bonds are present across the board. We will mostly focus on the UK both in the empirical motivation and in the theoretical specification due to the significant presence of inflation-indexed debt, as evidenced by figure 1.²

While ‘fiscal dominance’ in the sense of [Leeper \(1991\)](#) is not a predicament for an analysis of the role of government surplus behavior for inflation, it usually enhances the role of fiscal policy as drivers of inflationary dynamics in macroeconomic general equilibrium models ([Leeper, 1991](#); [Sims, 2011](#); [Ascari et al., 2023](#); [Bianchi et al., 2023](#)). Instead of providing a full picture supporting possible fiscal dominance,³ we motivate this paper by considering a specific policy example: the UK ‘mini-budget’ considered in September 2022, which can be considered an exogenous fiscal policy disturbance.⁴

Figure 2: Expectations of nominal interest rates in the United Kingdom for the three MPC meetings after the ‘mini-budget’ announced in September 2022. The dots at the end reflect the factual values of nominal policy rates after each meeting has taken place.

To indicate that this might be an example of a fiscal shock driving implications for monetary policy adjustment (and thus informing the fiscal-monetary mix through ‘fiscal dominance’), figure 2 plots the market-implied policy rates in the window around the mini-budget announcement and its cancellation. The first solid line depicts the date of a Bank of England MPC meeting, which occurred just ahead of the detailed policy announcement of the ‘mini-budget’ fiscal policy measure, with the MPC minutes being released on the 22nd of September 2022, one day ahead of the fiscal policy announcement. This is useful for our argument insofar as the meeting likely communicated

²Ex-post realized real yields differ between the two types of bonds as well, for instance due to inflation risk premia and liquidity risk premia ([Gürkaynak et al., 2010](#)). Looking at market yields at constant maturity, historical data provided by the [Fed Board of Governors \(2024\)](#) confirms a permanently positive differential in market yields on 10-year constant-maturity TIPS relative to standard US treasuries on every day since 2003.

³Relevant evidence for the UK, the US, and the Euro Area is provided by [Ascari et al. \(2024\)](#); [Barro and Bianchi \(2023\)](#); [Bianchi et al. \(2023\)](#); [Chen et al. \(2022\)](#); [Cochrane \(2022b\)](#); [Leeper \(2023\)](#); [Smets and Wouters \(2024\)](#).

⁴For a more detailed argument related to this fiscal shock, see [Leeper \(2023\)](#), [NIESR \(2022\)](#), and section 2.2.

the Bank of England’s stance on future rate changes clearly, taking all available information up to that point into account ([Braun et al., 2024](#)). Nonetheless, implied policy rates rose sharply a couple of days after the meeting of the Bank of England’s MPC, just after the announcement of the mini budget (denoted by the first dotted line), with the shift amounting to a 120bps increase in expected policy rates one year ahead. After the scraping of the mini-budget (second dotted line), expected policy rates swiftly returned to their ‘pre-shock’ levels.⁵

This event resonates well with the possible idea of (at least partial) fiscal dominance: financial market participants clearly expected changes to the monetary policy stance beyond the very short term in response to an announced fiscal policy measure.

Literature Review

This paper contributes to the burgeoning literature on fiscal-monetary interactions, pioneered in [Sargent and Wallace \(1981\)](#) and formalized through [Leeper \(1991\)](#). Initial contributions focusing on the possibility of fiscal dominance include [Sims \(1994\)](#) and [Woodford \(1995\)](#), who also coined the terminology behind the ‘Fiscal Theory of the Price Level’ (FTPL), whose mechanisms apply in the presented framework as well. More succinct summaries of the literature and of the state-of-the-art of the FTPL are provided by [Leeper and Leith \(2016\)](#) and [Cochrane \(2023\)](#). [Bassetto and Cui \(2018\)](#), [Liemen and Posch \(2022\)](#), and [Bianchi et al. \(2023\)](#) provide advances of the FTPL in standard OLG and New-Keynesian models, while empirical support for the possibility of fiscally-driven inflation has been developed in [Barro and Bianchi \(2023\)](#), [Cochrane \(2022a\)](#), [Chen et al. \(2022\)](#), and [Cloyne et al. \(2023\)](#), mirroring the interest in possible fiscal drivers in the recent inflationary episode. A narrative example of a recent fiscal shock informing inflation rates is provided by [Hazell and Hobler \(2024\)](#), who focus on the 2021 Georgia Senate election runoff.

Applications of fiscally-driven price level determination in recent papers shifted the focus towards models with an endogenous real interest rate. This is important insofar as such models fundamentally constitute criteria that constrains the *transversality condition* on government debt to hold for only *one* candidate price level, but that transversality condition itself fundamentally depends on the real interest rate. [Brunnermeier et al. \(2020\)](#), [Miao and Su \(2021\)](#), and [Kaplan et al. \(2023\)](#) each provide conditions under which such models nonetheless admit (unique) forward-looking equilibria expressed through the price level, however, their notions of uniqueness are challenged by [Hagedorn \(2021, 2024\)](#), who argues that the endogeneity of the real interest rate in incomplete-markets models ‘breaks’ determinacy and allows a continuum of initial price levels to exist. We contribute to this literature by explaining and partially overcoming this seeming discrepancy, qualifying the criteria under which we obtain unique price levels even in incomplete-market settings with inflation-indexed debt.

In a recent contribution closely related to the importance of transversality conditions (which, as

⁵Note that the expected monetary policy response was partially driven by a concurrent funding mismatch in liability-driven investment strategies of defined-benefit pension funds that were closely tied to movements in yields of sovereign bonds. See [Pinter \(2023\)](#) for a detailed exposition of this point.

we just mentioned, lie at the heart of fiscal price level determination), [Brunnermeier et al. \(2024\)](#) lays out how differences in the valuations of ‘safe’ assets can induce an aggregate transversality condition to fail, even if individual transversality conditions hold. We contribute to this idea by laying out the properties of this idea in a model of the fiscal price level determination with indexed debt, paying attention to the different insurance properties borne by both types of debt.

We also contribute to the literature on inflation-linked government bonds. Such bonds were introduced in economic and financial research long ago, especially in relation to the introduction of TIPS in the US in 1997. One of the earliest contributions in this field is [Fischer \(1975\)](#), who derives household demand for such assets in a multi-asset framework. The special insurance properties of such inflation-linked debt are extensively discussed in [Barr and Campbell \(1997\)](#), [Garcia and van Rixtel \(2007\)](#), [Gürkaynak et al. \(2010\)](#) and [Andreasen et al. \(2021\)](#). Notably, [Sims \(2013\)](#) briefly mentions the possible detrimental consequences of indexed debt in FTPL-type frameworks. This paper builds on his remarks, providing a rigorous framework nesting his intuitions. [Schmid et al. \(2024\)](#) provide a systematic analysis of inflation-indexed debt as a policy tool, emphasizing its role as an ex-ante commitment device against inflation. In our contribution, we leverage the unique properties of inflation-indexed debt, which express themselves mostly through the induction of a backward-looking component in the government budget equilibrium condition and through the insurance premia they bear. Our focus thus effectively rests on the ‘ex-post’ effects that inflation-indexed debt can have in the face of expansionary government spending shocks.

In the later sections of the paper, we majorly rely on modern computational methods to efficiently solve and estimate heterogeneous-agent methods, as in [Kaplan et al. \(2018\)](#), [Bayer and Luetticke \(2020\)](#), and [Achdou et al. \(2022\)](#). In particular, we leverage the efficient computation algorithms pioneered in [Auclert et al. \(2021\)](#) and some of the refinements of [Auclert et al. \(2024\)](#) to solve a model with heterogeneous households, two types of assets, and fiscal-monetary interactions in a matter of minutes.⁶

Finally, we are not the first to link fiscal-monetary interactions to heterogeneous-agent frameworks. [Brunnermeier et al. \(2020\)](#), [Kaplan et al. \(2023\)](#), and in particular [Kwicklis \(2024\)](#), who links fiscal dominance to the canonical HANK framework of [Kaplan et al. \(2018\)](#), have all applied fiscal price level determination to heterogeneous-agent frameworks. [Angeletos et al. \(2024\)](#), on the contrary, negate the need for FTPL-type elements, finding quantitatively identical responses of inflation to expansionary fiscal shocks in HANK models. Our contribution is to introduce a second type of assets (inflation-indexed debt) with a feedback loop between asset holdings and the price level, quantifying the importance that such indexed debt has for inflation dynamics in a calibrated state-of-the-art macroeconomic model. We furthermore show that non-Ricardian effects of fiscal policy arising through ‘fiscal dominance’ and non-Ricardian effects arising through market incompleteness as in HANK are generally *not* equal once we introduce inflation-indexed debt.

⁶To motivate the relevance of household heterogeneity applied to holdings of sovereign debt, figure E.1 in the appendix provides evidence on the skew of household holdings of such debt, sorted by their respective income decile. It furthermore establishes that this skew is *even more pronounced* for inflation-indexed debt.

The rest of the paper is structured as follows. Section 2 briefly exposes the relevance of indexed debt for bond revaluations and ex-post inflation in the face of fiscal shocks, after which we introduce inflation-indexed debt in simplified economic frameworks in sections 3 and 4. We introduce the main quantitative model in section 5. Section 6 discusses the calibration and estimation methods, and we present our quantitative findings in section 7. Finally, section 8 concludes.

2 The empirical importance of indexed debt for inflationary dynamics

To motivate the relevance of indexed debt as a possible driver of the net present value of government debt and, therefore, of price level dynamics through its budget valuation equation, we provide two pieces of evidence: first, we employ a long-running series of exogenously supplied fiscal policy shocks in a local projection applied to both the UK and the US to pin down the effects that inflation-indexed debt has on inflation itself when fiscal spending disturbances affect the economy. Second, we follow up on Hazell and Hobler (2024) and provide a narrative analysis of a specific fiscal shock in a high-indexed-debt environment, finding decisively larger inflation multipliers in response to deficit shocks.

To complement this picture, in appendix F we derive a measure of ‘net fiscal shocks’ in the UK with two types of sovereign debt under the assumption of *complete markets*, showing that the *unexplained* component of revaluations of sovereign debt, induced (among other things) by the complete markets assumption, is closely linked to the share of inflation-indexed debt in the government bond portfolio, which solidifies the need to consider interactions between incomplete-markets and the two types of debt.⁷

2.1 Evidence on the ex-post inflationary effect of inflation-indexed debt

We begin by providing direct evidence on the effect that inflation-indexed debt can have on inflation, making use of the series of narratively identified tax shocks provided by Mierzwa (2024).

We leverage his time series of exogenous fiscal policy surprises, and combine it with our novel long-running series of inflation-indexed debt, taking the share of inflation-indexed debt in the overall sovereign debt portfolio as our main indicator for the intensity of the prevalence of inflation-indexed debt. Equipped with these time series, we estimate the following local projection (Jordà, 2005) to measure the dynamic impact of inflation-indexed debt on changes in the rate of inflation:

$$\log P_{t+h} - \log P_{t-1} = \alpha_h + \beta_h \Delta \omega_t \varepsilon_t^F + \delta_{1h} \Delta \omega_t + \delta_{2h} \varepsilon_t^F + \Gamma_h Z_{t-1} + e_{t+h}, \quad (1)$$

where $h \geq 0$ indexes the forecast horizon considered and Z_{t-1} is a vector of control variables

⁷We limit ourselves to one country and one time period only in that appendix, focusing majorly on the importance of indexed debt while minimizing the need to account for cross-sectional heterogeneity. For a cross-country exercise *without* indexed debt that focuses directly on the empirical link between fiscal surprises and inflation, see Barro and Bianchi (2023).

specified below. Of particular interest to us is the coefficient β_h , which captures the cross-effect of the identified fiscal shock ε_t^F and the growth in the share of inflation-indexed debt $\Delta\omega_t$ present in the economy at time t .⁸ Of particular interest to us is the coefficient β_h , which captures the cross-effect of the identified fiscal shock ε_t^F and the share of inflation-indexed debt ω_t present in the economy at time t . In our estimation, we utilize the entire sample provided by Mierzwa (2024), i.e., from 1970 Q1 until 2019 Q2.

Figure 3: IRF implied by the local projection (1) through the coefficients β_h . The control vector Z contains the first four lags of the real GDP growth rate, the short-run UK bank rate, the change in the weighted real exchange rate, a same-period recession indicator, year-fixed effects, and the first lag of the price level difference. Standard errors are robust to heteroskedasticity and autocorrelation (Newey-West correction). Confidence intervals are provided at the 90% level. Sample length: 1970 Q1 - 2019 Q2.

Figure 3 depicts the impulse-responses from our preferred local projection specification. Crucially, we can observe a positive interaction effect between the share of inflation-indexed debt present in the economy and the fiscal policy shock, directly after the fiscal shock occurs. In economic terms, the coefficients imply that a 1% increase in the combined measure of the change of the share of inflation-indexed debt and the narratively identified fiscal shock (measured as a percentage of GDP) itself leads to an increase of the price level of almost 1% in the two years after the shock.⁹

2.2 Narrative evidence on shocks in high-indexed-debt environments: the 2022 UK ‘mini-budget’

Finally, we provide a piece of narrative evidence directly related to a clearly identified fiscal policy shock: the September 2022 UK fiscal policy announcement, commonly dubbed the ‘mini-budget’. We focus on this specific shock episode of the UK for two reasons: first, as we will argue now, the event was largely unexpected in terms of its magnitude, allowing us a clear identification of the

⁸We work with the growth rate of the share of inflation-indexed debt in the total debt portfolio to capture the effect of the joint variation in the indexed debt share and the fiscal spending behavior, postulating that previous levels of inflation-indexed debt are already accounted for in the government budget valuation equation prior to the shock occurring. Econometrically, we therefore simply follow Cloyne et al. (2023).

⁹Further details related to this analysis as well as an application to US data are provided in appendix E.

effects of fiscal shortfalls on inflation. Second, we view this exercise as a complement to [Hazell and Hobler \(2024\)](#), who exploit probabilistic variation on Democrat Senate control around the 2021 Georgia Senate run-off election to infer the expected effects of expansionary fiscal policy on the price level. We provide a similar exercise in an environment with high levels of inflation-indexed debt, complementing their existing estimates.

The institutional set-up of UK fiscal policy serves as an excellent device for identifying the 2022 ‘mini-budget’ episode as a clear fiscal shock. Fiscal policy in the UK is shaped by regular fiscal announcements, which set up the broad guidelines for expected sovereign income and spending in a given fiscal year. From 1980 until 2016, the larger ‘budget announcement’ would usually occur in early spring (coinciding with the beginning of a new fiscal year), supplemented by shorter budget statements in the fall of the same year. Between 2017 and 2019, the regular budget announcement was moved to fall, with the spring season being used usually for supplementary announcements. From 2020 onwards, the main budget statement was again placed in the early spring season.

In spring 2022, then-Chancellor Rishi Sunak provided a budget statement, which was followed up by a full budget announcement in November 2022. Inbetween, and therefore outside of the usual bi-annual statement/announcement rhythm, then-Chancellor Kwasi Kwarteng (who had since been appointed) presented a Ministerial Statement dubbed “The Growth Plan”, with fiscal policy measures amounting to 150 Billion GBP, or approximately 5% of the GDP of the United Kingdom ([NIESR, 2022](#)). This statement did *not* constitute a budget announcement in the usual sense, being placed outside of the bi-annual budget statement cycle. The release of all budget statements made by the British government is usually supplemented with a concurrently released report by the Office for Budget Responsibility (OBR), an independent auditor supervising budgetary questions in the United Kingdom. In the particular case of the ‘mini-budget’, no such independent forecast of the budgetary consequences of the statement was publicly released, as the ruling government denied the release of the concurrent forecast provided by the OBR.

The episode of early fall 2022 is characterized by this fiscal policy announcement and its expected effects. In particular, we are able to isolate the effects of the fiscal policy announcement from any monetary policy effects (both in terms of the policy level and in terms of the signaling of the state of the economy), since the preceding Bank of England Monetary Policy Committee decision was released one day *before* the announcement of the fiscal policy measure, on September 22, 2022.

2.2.1 The size of the shock

The most important question begets the *size* of the fiscal policy shock, which is *not* equal to the overall size of the fiscal announcement, as the fiscal policy announcement had been expected ahead of the final budget statement. Ignoring this would contribute to an upwards bias of the estimates of the effects of the policy announcement. Additionally, the probability of the fiscal policy measures being implemented upon announcement need not equal 100%, which might cause a downwards bias of our estimates.

To address these important questions, we follow the lead of [Hazell and Hobler \(2024\)](#), albeit with some limitations caused by impeded data availability. First, we establish the actual *full* size of the fiscal policy package through its direct impact on the budget. This serves as our factual upper bound of the size of the possible shock. Here, we utilize two estimates:

- The first is based on a direct reading of the corresponding budget statement.¹⁰ Algorithms summarizing the implied policy measures robustly predict that the “Debt Management Office’s Net Financing Requirement increasing from GBP 161.7 billion to GBP 234.1 billion in 2022-23”, such that the corresponding upper bound of the shock would be GBP 72.4 billion.
- The second is an analysis by the *Institute of Fiscal Studies*, which predicts “a GBP 60 billion hole in the budget”.¹¹

As alluded to above, the shock element impacting the expected path of debt and inflation on the day of the announcement was not equivalent to the full size of the announced measures. Instead, the announcement of the fiscal policy package was expected, but its full extent was simply not known. To arrive at estimates of the shock component to the expected fiscal funding shortfall, we are able to exploit forecasts on *Public Sector Net Borrowing*, which are aggregated on a monthly basis and released by the UK Treasury.¹² These are forecasts about the factual borrowing requirement of the government, provided both by financial market participants as well as otherwise independent forecasters. We collect data on the forecasts provided in the period between September 1, 2022, and September 22, 2022 (i.e., until the day before the shock) and we compare these forecasts with the ones collected between October 1, 2022, and October 10, 2022. Unfortunately, we lack data collected at narrower time intervals, but this would - if anything - cause a downwards bias of the estimated debt-price multiplier.¹³

For September 2022, the forecasts were provided by Barclays Capital, Netwest Markets, the British Chambers of Commerce, Beacon Economic Forecasting, CEBR, Liverpool Macro Research, and Oxford Economics. We observe a total mean forecast revision of Public Sector Net Borrowing for the 2022-23 and 2023-24 Fiscal Years of GBP 47.4 billion, vastly exceeding all other non-crisis period forecast revisions.¹⁴ This confirms our initial intuition that the ‘mini-budget’ shock was indeed economically significant and to a large degree unexpected. Given that this forecast revision is also below our upper bound of the shock size, we will work with this estimate of a GBP 47.4 billion funding shortfall, equivalent to 1.27% of annual GDP in 2022 (GBP 47.4 billion / GBP 3.732 trillion).

¹⁰The statement is available under <https://www.gov.uk/government/publications/the-growth-plan-2022-documents>.

¹¹The report is available under: <https://ifs.org.uk/articles/mini-budget-response>.

¹²The forecast summaries are available under <https://www.gov.uk/government/collections/data-forecasts>.

¹³The multiplier in terms of the influence of a change in sovereign borrowing on expected inflation is larger for a given change in expected inflation when the borrowing shock is *smaller*. Here, we are more likely to over-estimate the size of the ‘shock’ aspect, since we include data that is two weeks away from the fiscal announcement, by when financial markets might have already priced in more of the fiscal response.

¹⁴The only periods with larger absolute adjustments in the two-year budget deficit forecast were April 2020 (GBP 147.4 billion), May 2020 (GBP 114.9 billion), and May 2009 (GBP 50 billion). Outside of the GFC and Covid periods, the largest absolute month-on-month average forecast revision was GBP 20.8 billion in October 2019, vastly smaller than the forecast change in October 2022.

Relative to the fiscal shock analyzed in [Hazell and Hobler \(2024\)](#), our shock equals 60% of the size of their shock relative to local nominal annualized GDP. Unlike [Hazell and Hobler \(2024\)](#), however, we do not provide a discussion about the nature of the stimulus as we are mostly interested in the degree to which the stimulus coincided with changes to expected inflation.

2.2.2 Linking the deficit shock to expected inflation

We now introduce data capturing expected inflation from a standard high-frequency identification strategy that measures the expected inflationary consequence of the underlying stimulus. We follow [Hazell and Hobler \(2024\)](#) and postulate that around the ‘mini-budget announcement’ the dynamics of asset prices y_t can be summarized by the process:

$$y_t = \begin{cases} \varepsilon_t & \text{if } t < T, \\ \varepsilon_t + \alpha_t & \text{if } t \geq T, \end{cases} \quad (2)$$

where T denotes the time period at which fiscal stimulus occurred. We simply set our shock period to September 23, 2022, 09:30am, coinciding with the beginning of the budget statement in parliament. Denoting by j a counter of periods after the event, we can denote by $\hat{\alpha}_{T+j} = y_{T+j} - \mathbb{E}_T[y_{T+j} | \alpha_{T+j} = 0]$ the estimate of the causal effect of the shock in the narrow window around the announcement.

Figure 4: Implied inflation expectations from one-year GBP Inflation swaps in the period around the ‘mini-budget’ shock, with data normalized to 0 for September 23, 2022, 09:30am. The gray fan-chart depicts 68% and 95% confidence intervals for implied inflation based on a forecast of the swap price from the moment of the shock onward, with the model being chosen optimally in accordance with the Bayesian Information Criterion.

Our main quantity of focus is one-year ahead expected inflation, as implied through GBP-indexed inflation swaps traded at the London Stock Exchange.¹⁵ Figure 4 summarizes the movements of expected one-year ahead inflation around the ‘mini-budget shock’ on September 23, 2022, as implied by one-year ahead inflation swaps.

With the dashed vertical lines, we plot points at which we can expect to recover meaningful estimates about the response of one-year ahead inflation implied by financial markets. The first vertical line simply depicts the beginning of the shock, as implied by the beginning of the budget speech announcing the effects of the ‘mini-budget’. The second line measures one-year ahead inflation expectations on the same day at 3:00pm, 5.5 hours after the budget speech commenced. Even though we can credibly expect markets to take a couple of days to incorporate news into forming inflation expectations (Bahaj et al., 2023), we can already see a significant response of implied inflation on the same-day. Looking at the effect measured on the next trading day, we can observe a further magnification of the effect and an implied year-on-year inflationary response of 0.277% to the narratively identified shock.

Between the third and the fourth vertical line, we can observe a sharp drop in implied inflation. This is consistent with a growing expectation that the fiscal spending announcement might end up being unraveled. We provide a narrative description of the events in this period in appendix E.3, including a brief description of the role played by the troubles on LDI markets.

On September 28 & 29, we can see a significant up-shoot in the expected inflation measure. While by then other events might contaminate the evolution of inflation swap prices, the observed sharp appreciations perfectly coincide with statements of the Treasury that *despite* the market turmoil, the proposed fiscal package will be followed through, superseding previous statements of a release of a stabilizing medium-term fiscal plan. The elevated levels of expected inflation then continued to persist well into October, when an eventual unraveling occurred in parallel to an overhaul of the ruling government that enacted the fiscal package in the first place.

To remain conservative in terms of the implied size of the expected inflation adjustment, yet consistent with the literature, we postulate that the response of inflation swaps until September 26 can be considered the baseline change in one-year ahead inflation expectations.

The Inflation Multiplier: following our discussion, our baseline estimate of the one-year ahead inflation multiplier, which captures the response of year-on-year inflation to a 1% deficit-to-GDP shock, is therefore $0.277/1.27 \approx 0.22\%$. This exceeds the *two-year* inflation multiplier found by Hazell and Hobler (2024) of 0.19% by 15%. This is despite our assumptions ensuring that we achieve the most conservative estimate of the inflation multiplier that we can possibly obtain. Taking the point estimate of 0.603 (which aligns closest with the forecast change to the budget deficit introduced in the last subsection), the inflation multiplier would amount to $0.603/1.27 \approx 0.475\%$, more than double the estimate of Hazell and Hobler (2024) and vastly above existing estimates for

¹⁵Since inflation swaps operate with a two-month indexation lag in the context of the UK, we adjust the prices of the swaps to reflect this lag, again in line with Hazell and Hobler (2024).

other countries.

Finally, the effects of the shock were expected to be relatively persistent, as implied by inflation swaps for longer horizons depicted in figure 5.

Figure 5: Implied inflation expectations for various forecast horizons, as implied by GBP inflation swaps on September 26, 2022, 12:00pm. 95% confidence bands are indicated.

In appendix section E.3 we provide some further evidence on the nature of the ‘mini-budget shock episode’, which confirms an element of surprise in relation to the size of the unveiled fiscal package that contributed to the turmoil on financial markets reflected in the pricing of inflation swaps.

Equipped with all evidence on the effects of inflation-indexed debt on both the revaluation of sovereign debt and inflation, we now introduce inflation-indexed debt in simplified economic frameworks to lay out the mechanisms under which such debt operates in canonical models.

3 Intuition from a simplified model

Introducing inflation-indexed debt in a one-equation price level-determination model

We first explicitly introduce inflation-indexed debt in the government budget valuation equation, which therefore effectively constitutes a partial equilibrium analysis focusing on the importance of the government budget for price level dynamics. We derive the novel result that the price level itself becomes a *state variable* in the intertemporal government budget equilibrium, i.e., today’s price level becomes a function of the past price level. This is despite the lack of other inertia, and it gives rise to a double role of the price level as a state variable and a market-clearing jump variable.

We begin by deriving the intertemporal government budget equilibrium with indexed debt, starting off with the case of ‘fair’ bond pricing, i.e., abstracting from insurance premia on either type of debt. The per-period government budget constraint in a world with indexed debt is given by

$$B_{t-1} + \frac{P_t}{P_{t-1}} b_{t-1} = P_t s_t + Q_t B_t + q_t b_t,$$

where notation follows the previous section, i.e., B_t denotes the terminal value of non-indexed government debt issued at time t at a price Q_t , lowercase letters correspond to the values for inflation-indexed debt, s_t are net real surpluses raised, and P_t denotes the price level. The cost of maturing inflation-indexed debt b_{t-1} is scaled by the gross inflation rate, P_t/P_{t-1} .¹⁶

To close this model as simply as possible, we let $Q_t = \frac{1}{1+i_t}$ and $q_t = \frac{1}{1+r_t}$, i.e., the price of bonds equals the inverse of their respective relevant gross interest rate. By using the real interest rate to determine the price of inflation-indexed debt, we factually take into account expectations on the payment being indexed to the ex-post inflation rate.¹⁷ Iterating this equation forwards after dividing both sides by P_t and making use of the Fisher equation, we find the following relationship:

$$\frac{B_{t-1}}{P_t} + \frac{b_{t-1}}{P_{t-1}} = \sum_{j=0}^{\infty} \prod_{l=1}^j \frac{1}{1+r_{t+l}} s_{t+j}. \quad (3)$$

This is the simple intertemporal budget equilibrium with indexed debt, but without accounting for the differences in the insurance properties borne by the two types of debt, which allowed us to make use of the simplified bond pricing kernels Q_t and q_t as defined in the last paragraph.¹⁸ Indeed, *the price level itself becomes a state variable*: the real value of maturing inflation-indexed bonds depends on the past price level, not on today's price level. Intuitively, the real value of inflation-indexed bonds depends on the past price level, because the face value payment of that bond is unity at *yesterday's prices*. The term in orange is the novel addition relative to canonical models of fiscal inflation and is the centerpiece of this paper.

Sample IRFs in partial equilibrium with finite horizon

We now briefly explore the properties of this intertemporal budget equilibrium relationship using impulse-responses to the price level under various levels of inflation-indexed debt (as derived above in equation (3)). The goal is to explore how indexed debt changes the mechanisms inducing fiscal inflation in relation to surplus shortages in the clearest possible way.

We set up the model (in terms of outstanding bonds and expected surpluses), such that $P_{-1} = 1$. The initial state is therefore the one in which the PDV of surpluses is equal to the real value of the stock of debt in each period. The economy has a finite horizon of 11 periods $t \in \{-1, 0, 1, \dots, 9\}$, such that all debt has to be repaid by the government in period 9 by appropriate surpluses. This

¹⁶See [Hilscher et al. \(2022\)](#) and [Schmid et al. \(2024\)](#) for recent contributions using the same definition of non-indexed and indexed debt.

¹⁷Possible insurance premia on inflation-indexed debt will be introduced later in general equilibrium.

¹⁸Effectively, due to the Fisher equation, the above bond pricing kernels impose the absence of any insurance premia or other valuation wedges, allowing both types of bonds to yield exactly the same realized returns. Section 5 discusses in more detail bond pricing kernels *without* this simplification.

setup ensures a price level of $P_t = 1 \forall t$ in the absence of any shocks. The impulse to the system is a one-period decrease of surpluses by 10% in period 0, announced at the same time. After the shock period, the PDV of surpluses will therefore return to its pre-shock value.

IRFs of the price level to a 10% one-period surplus shock at $t = 0$

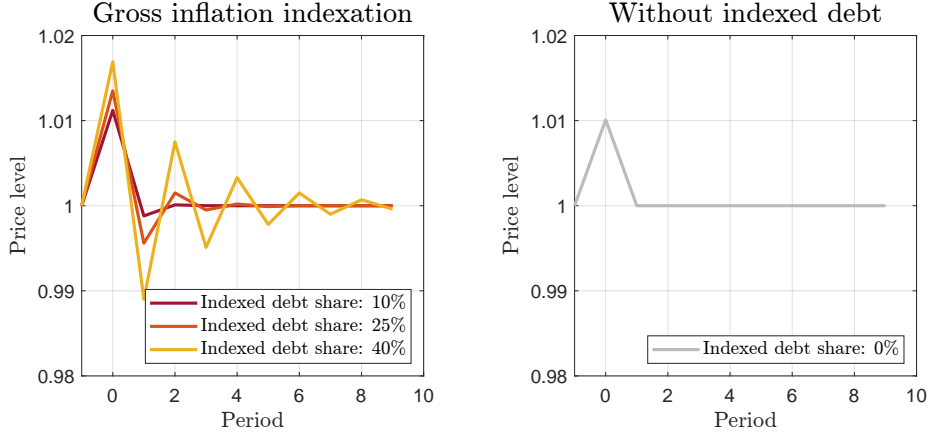

Figure 6: IRFs to a 10% decrease in one-period surpluses in $t = 0$ conditional on the share of indexed debt.

Figure 6 highlights the reaction of the price level in response to a decrease in surpluses in period 0, announced in the same period. The right-side panel illustrates the “standard” response induced by the government budget valuation equation in a world without inflation-indexed debt. In period 0, the decrease in real surpluses induces a temporary upwards adjustment of the price level proportional to the decrease in surpluses, which returns back to its initial state subsequently, since the PDV of surpluses is equal to the pre-shocked value from period 1 onwards.

However, when we have a strictly positive share of inflation-indexed debt, the impact response is exacerbated: given that the initial price level P_{-1} is fixed in the moment of the policy announcement at time 0, it is not possible to devalue the stock of inflation-indexed debt when the shock occurs. Therefore, the devaluation of the remaining (non-indexed) stock of bonds must be *larger* relative to the case without inflation-indexed debt: the price level must go up by a larger amount in the shock period when we have inflation-indexed debt.

The periods following the shock yield further exciting dynamics that are not observed under a ‘standard’ FTPL-style model as in the right panel. Instead of returning to the pre-shock value once the shock vanishes, we can observe oscillating behavior of the price level when indexed debt is present in the economy. Since from $t = 1$ onwards the PDV of surpluses returns to its pre-shock level, we are in a situation in $t = 1$ in which the stock of debt is suddenly worth *too little*: inflation-indexed debt is not worth much due to the high price level at $t = 0$, which is the correct factor to adjust such debt to ‘real’ terms in period 1. But since the funding shortfall is now gone, this implies that the real value of non-indexed debt (B_1/P_1) must actually *increase* to make up the ‘under-valuation’ of indexed debt: therefore, P_1 must *decrease* (increasing the real value of non-indexed debt) to let the government budget equilibrium hold. In the subsequent period, the price

level from the previous period is now *too low*, increasing the value of indexed debt and pushing down the real value of non-indexed debt through a higher price level. This mechanism repeats itself until convergence to the initial equilibrium.¹⁹

IRFs of the price level to a 10% one-period surplus shock at $t = 4$

Figure 7: IRFs to a 10% decrease in one-period surpluses in $t = 4$ conditional on the share of indexed debt.

Figure 7 repeats the above exercise for a similar decrease of surpluses at a later time (in period 4), announced in period 0. Due to the early announcement, the PDV of surpluses already decreases in period 0, remaining below its initial value until period 4, inclusive. The oscillations induced by inflation-indexed debt decrease in size until period 4 (after being larger immediately following the announcement in period 0), and subsequently pick up from period 4 onwards in line with the mechanism described above. The fact that the oscillations are decreasing in magnitude leading up to the shock is caused by the PDV of surpluses *not* being constant between periods 0 and 4 in this example: the closer we get to period 4, the more the PDV of surpluses actually decreases, because we get closer to the period with the smaller surpluses and thereby discount that period less and less. This buffers the price level oscillations on our way to the period of the shock.

A further exposition of the importance of inflation-indexed debt within the context of a simple macroeconomic model (akin to [Leeper \(1991\)](#)), including a brief discussion of the determinacy properties, can be found in appendix C.

4 A dis-equivalence between HANK and Fiscal Dominance

A recent contribution by [Angeletos et al. \(2024\)](#) claims through an insightful tractable ‘quasi-HANK’ framework that the effects of active fiscal policy in a joint monetary-fiscal policy framework can be replicated, up to first order, by a tractable quasi-HANK model, as both models induce a form of Ricardian dis-equivalence, but can be parametrized in a way that achieves the same effect

¹⁹[Cochrane \(2001\)](#) explores a similar result in figure 4 of his paper, driven by a non-geometric maturity structure and the presence of long-term debt.

irrespective of the modeling device chosen. In a sense, this refutes the necessity for considering monetary-fiscal interactions in ways moving beyond monetary policy rules adhering to the Taylor Principle and, thereby, the need to invoke the 'FTPL' as a limiting condition pinning down sustainable paths of government debt altogether.

This matters for our presented contribution, as the simultaneous consideration of market imperfections commonplace in HANK models that induce Ricardian dis-equivalence might suffice to generate the mechanisms we intend to capture. We briefly leverage the modeling framework presented by Angeletos et al. (2024) to refute this criticism, providing evidence that under the presence of inflation-indexed debt the mere consideration of non-Ricardian elements inherent to heterogeneous-agent models mask effects that matter *only* in cases of fiscal dominance. This, in turn, lays the analytical groundwork for our later claim that the monetary-fiscal policy mix determines the extent to which government surplus shocks are becoming more inflationary in the share of inflation-indexed debt present in the economy.

As the model framework used for this analytical exercise mainly relies on the contribution of Angeletos et al. (2024) with minor adjustments to the fiscal and monetary policy rules that simply reflect that policymakers care about interest rates faced and taxes paid by *households*, we relegate the concrete derivations to Appendix D. We can summarize our main finding about the *relevance* of inflation-indexed debt in breaking the equivalence between fiscal dominance and HANK-type mechanisms of breaking Ricardian Equivalence in the following proposition:

Proposition 1 Let $\pi_{\epsilon,0}^{FD,RANK}$ denote impact inflation in Angeletos et al. (2024) with inflation-indexed debt, no quasi-heterogeneity, and under fiscal dominance; and let $\pi_{\epsilon,0}^{MD,HANK}$ denote impact inflation with inflation-indexed debt, quasi-heterogeneity, and under monetary dominance. Let κ be the slope of the Phillips curve, θ the share of inflation-indexed debt, τ_y the fiscal policy rule reaction parameter to output deviations from steady-state, β the discount rate, and ω the mortality risk of a given household discriminating whether an economy is considered to be of type 'RANK' ($\omega = 1$) or 'HANK' ($\omega < 1$).

If either of the following sets of conditions hold:

$$\frac{\kappa\theta + \tau_y}{\kappa}(1 - \beta\omega) - \theta > 0 \quad \& \quad \frac{\kappa\theta + \tau_y}{\kappa}(1 - \beta) - \theta > 0, \quad (4)$$

$$\frac{\kappa\theta + \tau_y}{\kappa}(1 - \beta\omega) - \theta > 0 \quad \& \quad \frac{\kappa\theta + \tau_y}{\kappa}(1 - \beta) - \theta < 0, \quad (5)$$

then impact inflation in response to an expansionary fiscal shock is higher in the policy limit point where fiscal and monetary dominance collapse ($\tau_d \rightarrow 0, \phi \rightarrow 0$) for the Fiscal Dominance-RANK economy relative to the Monetary Dominance-HANK economy, i.e., $\pi_{\epsilon,0}^{FD,RANK} > \pi_{\epsilon,0}^{MD,HANK}$.

Proof. See appendix D. ■

For most common calibrations (including the ones preferred by Angeletos et al. (2024)), this condition is fulfilled, which we plot in figure 8. In particular, the first of the two inequalities in the proposition is likely to be fulfilled as τ_y/κ is a large number for common calibrations of the fiscal

rule and the Phillips Curve parameter, including Angeletos et al. (2024). Only for very large values of θ relative to τ_y the reverse might be possible.

Figure 9 drives home the last point for the exact same calibration used in the quantitative model of Angeletos et al. (2024) for moderate levels of inflation-indexed debt ($\theta = 0.1$). Impact inflation is indeed higher in the Fiscal Dominance limit point without heterogeneity, with the differences being markedly stark at points close to the RANK economy.

Figure 8: Plot showing under which conditions either of the sets of inequalities described by proposition 2 is fulfilled and inflation is higher under FD-RANK than under MD-HANK. The dark green area denotes places where the first inequality is fulfilled, the light green area (on the top right) denotes places where the second set of inequalities is fulfilled, and the red area denotes places where neither of the sets of inequalities hold. The calibration follows of Angeletos et al. (2024): $\tau_y = 0.33$, $\kappa = 0.0125$, $\beta = 0.99$.

Figure 9: The impact of mortality risk (household heterogeneity) on inflation in the policy limit point where $\tau_d = 0$, $\phi = 0$.

While this brief analysis provides an exact qualitative statement on the need to move beyond the introduction of Ricardian Dis-equivalence when analyzing the consequences of inflation-indexed debt, a full quantitative HANK model serves as a better device to determine the size of the effects. With this motivation in mind, we now introduce our main quantitative model.

5 Fiscal-Monetary Interactions and the the government budget equation with heterogeneous households and indexed debt

Having studied the relevance of indexed debt in simplified models, we now introduce inflation-indexed debt in a state-of-the-art macroeconomic model. Given that inflation-indexed debt delivers desirable insurance features to households by providing an income smoothing source that yields a constant value in real terms, the chosen model must necessarily bear relevance to imperfect consumption smoothing, borrowing constraints, and market imperfections precluding perfect risk-sharing across households. We choose to work with a heterogeneous-agent model in the spirit of [Kaplan et al. \(2018\)](#), utilizing the efficient algorithms for solving the model provided by [Auclert et al. \(2021\)](#) and paying close attention to limitations of determinacy in incomplete-market models as exposed by [Brunnermeier et al. \(2024\)](#), which are intimately related to the determinacy-establishing properties that arise from analyzing the intertemporal government budget constraint.²⁰

Households: We index heterogeneous households by i . Such households choose consumption, c_{it} , labor supply, N_{it} , and asset holdings B_{it} and b_{it} to maximize their cumulative discounted utility

$$\mathbb{E}_0 \left[\sum_{t=0}^{\infty} \beta^t (u(c_{it}) - v(N_{it})) \right]$$

subject to two budget constraints - one for the aggregate household budget, and one for the semantically separate evolution of indexed debt:

$$P_t c_{it} + Q_t B_{it} = \frac{e_{it}^{1-\theta}}{\int e_{it}^{1-\theta} di} (1 - \tau_{it}) W_t N_{it} + B_{i,t-1} - d_{it} \mathbb{1}_{\{adj_{it}=1\}},$$

$$q_t b_{it} = \Pi_t b_{i,t-1} + d_{it} \mathbb{1}_{\{adj_{it}=1\}},$$

where Q_t and q_t are the nominal prices for non-indexed and indexed debt, respectively, whose holdings are denoted by B_{it} and b_{it} . $W_{it} \equiv w_{it} P_t$ denotes the nominal wage level, adjusted by hours worked N_{it} and scaled by the idiosyncratic productivity disturbance $\frac{e_{it}^{1-\theta}}{\int e_{it}^{1-\theta} di}$ and taxes τ_{it} . d_{it} captures idiosyncratic transfers from non-indexed bond holdings to indexed bond holdings, which are only allowed to happen when the exogenous portfolio rebalancing variable adj_{it} is equal

²⁰[Auclert et al. \(2024\)](#) furthermore provide analytical conditions for determinacy in economies with many bond types and bonds-in-the-utility function. We sidestep such an approach for now, recognizing its importance for future research.

to 1.²¹ Finally, households are also subject to standard borrowing constraints

$$B_{it} \geq -\underline{B}, \quad b_{it} \geq -\underline{b}.$$

Effectively, we posit that consumption is only possible directly from the non-indexed savings portfolio, i.e., we postulate that indexed debt cannot be transformed to consumption as easily as non-indexed debt. This assumption reflects the significantly smaller liquidity of inflation-indexed bond markets, even relative to their market size (Andreasen et al., 2021; Fleming and Krishnan, 2012) and is required for the ex-ante expected yields of both types of debt to be different. Without any adjustment friction, expected yields would equalize and there would be no incentive to hold both types of debt through a no-arbitrage argument.²²

To solve the household block, the crucial determinant will be whether a household will be able to adjust its holdings of indexed debt in a given period ($adj_{it} = 1$) or not ($adj_{it} = 0$). In the following, let $\varepsilon_i \equiv \frac{e_i^{1-\theta}}{\int e_i^{1-\theta} di}$ be a simplified descriptor of the Markov chain pinning down idiosyncratic productivity. We now define corresponding value functions for households, noting that the state variables are therefore the household-specific past asset holdings (B_-, b_-), the Markov chain realization ε_i , and the adjustment state adj_i . We drop the subscript i in the following for notational simplicity. We then find the following value functions:

- adjuster, $adj = 1$:

$$V_t(1, \varepsilon; B_-, b_-) = \max_{c, B, b, N} u(c) - v(N) + \beta \mathbb{E} [V_{t+1}(adj', \varepsilon', B, b) | \varepsilon] \quad (6)$$

subject to the budget constraint and the borrowing constraints:

$$Pc + QB + qb = \varepsilon(1 - \tau)WN + B_- + \Pi b, \\ B \geq -\underline{B}; \quad b \geq -\underline{b},$$

where adj' is i.i.d., with probability $\mathbb{P}(adj' = 1) = \nu$.

- non-adjuster, $adj = 0$: Here, b does not enter the decision set and is taken to be a state operating in the background, with the next-period income from non-indexed debt being automatically adjusted based off previously held indexed debt.

$$V_t(0, \varepsilon, B_-, b_-) = \max_{c, B, N} u(c) - v(N) + \beta \mathbb{E} \left[V_{t+1} \left(adj', \varepsilon', B, \frac{\Pi}{q} b_- | \varepsilon \right) \right] \quad (7)$$

²¹Such Calvo-type sticky debt arrangements have been present in macroeconomic models for a long time, see, e.g., Graham and Wright (2007), and have prominently been used in heterogeneous-agent models by Auclert et al. (2024) and Bayer et al. (2024).

²²Evidence on the use of inflation-indexed government bonds by households for inflation hedging within the context of the US is provided by Nagel and Yan (2022).

subject to the budget and borrowing constraints:

$$Pc + QB = \varepsilon(1 - \tau)WN + B_-,$$

$$B \geq -\underline{B}.$$

The goal is to recover policy functions $c(\cdot), B(\cdot), b(\cdot)$, and $N(\cdot)$ that solve the household problem in both instances. The above problem generally yields first-order conditions that depend on the adjustment possibilities that an agent enjoys in a given period. Denote by λ_{it}, μ_{it}^B , and μ_{it}^b the respective state-dependent constraint multipliers. For the adjusters, $adj_{it} = 1$, the relevant first-order conditions from that household problem are given by

$$\begin{aligned} \{c\} : & \quad u'(c) = P\lambda_{it} \\ \{N\} : & \quad v'(N) = \lambda_{it}\varepsilon(1 - \tau)wP \\ \{B\} : & \quad Q\lambda_{it} = \beta\mathbb{E}[V_{B,i,t+1}] + \mu_{it}^B \\ \{b\} : & \quad q\lambda_{it} = \beta\mathbb{E}[V_{b,i,t+1}] + \mu_{it}^b, \end{aligned}$$

while the envelope conditions, using $\lambda_{it} = \frac{u'(c)}{P}$ from the first-order condition on c , are given by:

$$\begin{aligned} V_{B,i,t} &= \frac{u'(c)}{P}, \\ V_{b,i,t} &= \begin{cases} \frac{u'(c)}{P}\Pi = \frac{u'(c)}{P_-} & \text{if } adj_{it} = 1 \\ \beta\frac{\Pi}{q}\mathbb{E}[V_{b,i,t+1}] & \text{if } adj_{it} = 0. \end{cases} \end{aligned}$$

The conditions for equilibrium jointly imply the following Euler equations:

$$\begin{aligned} \frac{Q}{P}u'(c) &\geq \beta\mathbb{E}[V_{B,i,t+1}], \\ \frac{q}{P}u'(c) &\geq \beta\mathbb{E}[V_{b,i,t+1}], \\ v'(N) &= u'(c)\varepsilon(1 - \tau)w, \end{aligned}$$

where the inequalities are strict if the respective asset holdings are at their respective lower bound.

This household block also clearly defines pricing kernels for the bonds that are on offer by the government, conditional on the households pricing the bonds being unconstrained. For non-indexed debt, the first-order conditions for households on the Euler equation imply that

$$Q_t = \beta\mathbb{E}_t\left[\frac{u'(c_{i,t+1})}{u'(c_{it})}\frac{P_t}{P_{t+1}}\right] := \mathbb{E}_t[M_{i,t,t+1}], \quad (8)$$

where M denotes the household-specific stochastic discount factor (SDF). For indexed bonds, applying the definition of the SDF,

$$q_t = \beta \mathbb{E}_t \left[\frac{u'(c_{i,t+1})}{u'(c_{it})} \right] = \mathbb{E}_t [\mathcal{M}_{i,t,t+1} \Pi_{t+1}]. \quad (9)$$

Firms and production

To focus on the effects of indexed debt and its interaction with households facing uninsurable idiosyncratic income risk, we model the production block in a parsimonious yet tractable way, following [Auclert et al. \(2024\)](#). In particular, we require in the following that the aggregate effects of idiosyncratic productivity risk are ‘small’ for the production firms relative to the aggregate effects of aggregate risks.²³

There exists a continuum of monopolistically competitive firms k that produce goods of variety k , which make each use of a linear production function $Y_{kt} = A_{kt}N_{kt}$. A_{kt} evolves according to an AR(1) process in logs,

$$\log A_{kt} = \rho_a \log A_{k,t-1} + \sigma_\epsilon \epsilon_{kt},$$

where we note that $0 \leq \rho_a \leq 1$. The firm profit function is standard and defined as

$$D_{kt} = \frac{P_{kt}}{P_t} Y_{kt} - \frac{W_t}{P_t} N_{kt} = \left(\frac{P_{kt}}{P_t} - \frac{W_t}{P_t} \frac{1}{A_{kt}} \right) A_{kt}^{1-\zeta} \left(\frac{P_{kt}}{P_t} \right)^{-\zeta} Y_t.$$

Following [Auclert et al. \(2024\)](#), a log-linearized approximation to the solution of the profit-maximization problem of monopolistically competitive firm yields a Phillips Curve of the form:

$$\hat{\pi}_t = (\varphi + \sigma) \kappa \sum_{l=0}^{\infty} \beta^l \hat{y}_{t+l} \quad (10)$$

where $(\varphi + \sigma)$ is the sum of the Frisch elasticity of labour supply and the inverse of the elasticity of intertemporal substitution, as in standard New Keynesian models.

Fiscal policy: We next move on to deriving the intertemporal government budget equilibrium in this economy. Recall from the introduction that this condition is fundamentally a criterion related to nominal determinacy through the transversality condition on government debt. This is the extent to which ‘FTPL’-type mechanisms are present in this model (as in most macroeconomic models), since the FTPL equation merely implies a relationship on government debt under which the transversality condition on government debt can only hold for one price level in a given period (see [Cochrane \(2023\)](#) and [Hagedorn \(2024\)](#) for a more detailed discussion of this point). However, as pointed out by [Brunnermeier et al. \(2024\)](#), individual transversality conditions on household

²³See proposition 4 of [Auclert et al. \(2024\)](#) for a detailed exposition of this point.

asset holdings do *not* imply that a similar transversality condition holds necessarily for aggregate debt stocks under incomplete markets. Therefore, with incomplete markets and endogenous real interest rates, the government budget valuation equation may ultimately fail to deliver a unique price level based off the aggregate 'transversality condition' on government debt, since there is no guarantee that such a condition holds in aggregate when markets are incomplete.

To illustrate this point, we first naively start from the government budget constraint, aiming to derive an integrated version of it in the hopes of finding a unique debt valuation equation.

$$B_{t-1} + \Pi_t b_{t-1} = P_t s_t + Q_t B_t + q_t b_t$$

is the standard government budget constraint, given some surplus schedule s_t and bond pricing kernels Q_t, q_t . We multiply all elements by the unweighted average household SDF $M_{t,t+1}$ and divide all elements by the current price level P_t to obtain

$$M_{t,t+1} \frac{B_{t-1}}{P_t} + M_{t,t+1} \frac{b_{t-1}}{P_{t-1}} = M_{t,t+1} s_t + Q_t M_{t,t+1} \Pi_{t+1} \frac{B_t}{P_{t+1}} + q_t M_{t,t+1} \frac{b_t}{P_t}.$$

Adding and subtracting elements suitably on the right-hand side, we re-express this equation as:

$$\begin{aligned} M_{t,t+1} \frac{B_{t-1}}{P_t} + M_{t,t+1} \frac{b_{t-1}}{P_{t-1}} &= M_{t,t+1} s_t + (Q_t M_{t,t+1} \Pi_{t+1} - M_{t+1,t+2}) \frac{B_t}{P_{t+1}} \\ &\quad + (q_t M_{t,t+1} - M_{t+1,t+2}) \frac{b_t}{P_t} + M_{t+1,t+2} \left(\frac{B_t}{P_{t+1}} + \frac{b_t}{P_t} \right). \end{aligned}$$

Iterating on this expression until T , dividing the resulting expression by the SDF, and taking limits $T \rightarrow \infty$, we end up finding:

$$\begin{aligned} \frac{B_{t-1}}{P_t} + \frac{b_{t-1}}{P_{t-1}} &= \mathbb{E}_t \left[\sum_{l=0}^{\infty} \frac{M_{t+l,t+l+1}}{M_{t,t+1}} s_{t+l} + \frac{Q_{t+l} M_{t+l,t+l+1} \Pi_{t+l+1} - M_{t+l+1,t+l+2}}{M_{t,t+1}} \frac{B_{t+l}}{P_{t+l+1}} \right. \\ &\quad \left. + \frac{q_{t+l} M_{t+l,t+l+1} - M_{t+l+1,t+l+2}}{M_{t,t+1}} \frac{b_{t+l}}{P_{t+l}} \right] + \lim_{T \rightarrow \infty} \frac{M_{T+1,T+2}}{M_{t,t+1}} \left(\frac{B_T}{P_{T+1}} + \frac{b_T}{P_T} \right). \end{aligned} \quad (11)$$

Note that this expression nests the standard FTPL case under complete markets, since in this case $Q_t M_{t,t+1} \Pi_{t+1} = M_{t+1,t+2}$ and $q_t M_{t,t+1} = M_{t+1,t+2}$.

Seeing this integrated government budget constraint, one could mistakenly believe that the current price level is determined by this equation, conditional on the previous price level P_{t-1} . This logic requires the last limiting term to vanish and go to zero. However, this is *not* necessarily the case: even though the transversality condition holds on the household level as a consequence of household optimality and a no-Ponzi condition, it *cannot* be aggregated to derive a concurrent aggregate transversality condition directly off-the-shelf: the reason for that is that the unweighted average SDF $M_{t,t+1}$ is discarding the heterogeneity of underlying consumption (which led to the rise of

household-specific discount factors), and thus ignores the possibility of the government possibly earning an excess return on its debt issuance. This can be considered a ‘safe asset premium’ (Brunnermeier et al., 2024) and is reflective of the inherent value that such debt bears to households in partially overcoming the market incompleteness, possibly yielding different ‘fundamental’ valuations of government debt by the household vis-à-vis the government.

Instead, we can follow the approach undertaken in Brunnermeier et al. (2024), which is dubbed the *dynamic trading perspective*, and aggregate household unit-level budget constraints to obtain a dynamic aggregate constraint on sovereign debt, which factually is a mirror image of the usual FTPL equation. Accounting for the benefits of the two debt products in partially overcoming market incompleteness borne by households, and thereby being able to leverage household-level transversality conditions, we find that we can still express the intertemporal budget equilibrium in terms of the real value of today’s debt holdings and a suitably-discounted surplus term:

Proposition 2 *In a model with both non-indexed and inflation-indexed debt and incomplete markets, the integrated government budget constraint (‘the FTPL equation’) can be expressed as:*

$$\frac{B_{t-1}}{P_t} + \frac{b_{t-1}}{P_{t-1}} = \mathbb{E}_t \left[\sum_{k=0}^{\infty} \tilde{M}_{t,t+k} \bar{A}_{t+k} \right], \quad (12)$$

where $\tilde{M}_{t,t+k} = \sum_i M_{i,t,t+k} \Pi_{t,t+k+1} \frac{A_{i,t+k}}{\bar{A}_{t+k}}$ is the weighted average SDF across all households i , adjusted for inflation, with weights being proportionate to $A_{i,t+k}$. $\bar{A}_t = \frac{1}{N_t} \sum_i A_{it}$ is the average of the term A_{it} , which captures the surpluses raised by the government from each household i and the utility-weighted windfall gain that households enjoy when holding inflation-indexed debt:

$$A_{it} \equiv c_{it} - \varepsilon_{it}(1 - \tau_{it})w_t N_t + [\text{Cov}_t(M_{i,t,t+1}, \Pi_{t+1}) + M_{i,t,t+1}(\mathbb{E}_t \Pi_{t+1} - \Pi_{t+1})] \frac{b_{it}}{P_t}.$$

Proof. See appendix A.1. ■

A_{it} therefore also expresses the full portfolio return of household i of holding an additional unit of net worth, consisting of the net utility gain from saving, the insurance premium on indexed debt (captured through the covariance term), and the possible windfall gain/loss from surprise inflation through indexed debt (captured through the last term). Equation (12) is ‘the FTPL equation’ that is used to pin down the price level at time t , given some previous price level P_{t-1} .

Maintaining this equation as determining the price level, we close the government block by assuming a simple taxation rule as in standard Fisherian models (see, e.g., section C in the appendix),

$$\frac{\tau_t}{\tau} = \left(\frac{s_{B,t-1}}{s_B} \right)^{\gamma_B} \left(\frac{s_{b,t-1}}{s_b} \right)^{\gamma_b} e^{\zeta_t}, \quad (13)$$

where $\tau_t \equiv \frac{T_t}{Y_t}$ are surpluses raised by the government as a fraction of output, and $s_{B,t} \equiv \frac{Q_t B_t}{P_t Y_t}$, $s_{b,t} \equiv$

$\frac{q_t b_t}{P_t Y_t}$ are the real market values of the two existing types of debt. ζ_t is a standard AR(1) shock to the quantity of lump-sum taxes raised, and the policy reaction coefficients to deviations of the market values of both types of debt from their steady-state values are given by γ_B and γ_b . Steady-state values are denoted without time subscripts. In log-linearized terms, this relationship is given by:

$$\hat{\tau}_t = \gamma_B \hat{s}_{B,t-1} + \gamma_b \hat{s}_{b,t-1} + \zeta_t. \quad (14)$$

Monetary policy: We allow monetary policy to follow an inertial Taylor rule with positive weights on both inflation and output deviations from steady-state:

$$\left(\frac{R_t^n}{R^n} \right) = \left(\frac{R_{t-1}^n}{R^n} \right)^{\rho_M} \left[\left(\frac{\Pi_t}{\Pi} \right)^{\phi_\pi} \left(\frac{Y_t}{Y} \right)^{\phi_y} \right]^{1-\rho_M} e^{\nu_t} \quad (15)$$

where ν_t is an AR(1) shock to the conduct of monetary policy. In exact log-linearized terms,

$$\hat{r}_t^n = \rho_M \hat{r}_{t-1}^n + (1 - \rho_M) [\phi_\pi \hat{\pi}_t + \phi_y \hat{y}_t] + \nu_t. \quad (16)$$

Market clearing: Finally we define market clearing on the three markets of relevance in this economy as follows:

- Goods market: on the goods market, aggregate consumption and production are equalized, taking into account the loss from price adjustment costs on the producer's behalf:

$$C_t + G_t + \frac{\mu/(\mu-1)}{2\kappa} (\log(1 + \pi_t))^2 Y_t = Y_t. \quad (17)$$

- Labor market: labor supply and demand must be equalized:

$$\sum_i N_{it} = \sum_k N_{kt}. \quad (18)$$

- Asset market: for each class of assets, the supply by the government must be equal to cumulative household demand:

$$B_t = \sum_i B_{it} \quad (19a)$$

$$b_t = \sum_i b_{it}. \quad (19b)$$

Equilibrium: We characterize a competitive equilibrium in this economy as follows:

Definition 1 (Competitive Equilibrium) A competitive equilibrium of the heterogeneous-agent economy is an allocation $\{C_t, N_t, Y_t, B_t, b_t, Y_{it}, N_{it}, d_t, \tau_t\}_{t=0}^\infty$, together with prices $\{P_t, P_{it}, w_t, \pi_t, Q_t, q_t, R_t^n\}_{t=0}^\infty$ and exogenous variables $\{\nu_t, Z_t, G_t\}_{t=0}^\infty$, such that:

- all agents maximize their utility with suitable policy functions on $c(\cdot)$, $N(\cdot)$, $B(\cdot)$, and $b(\cdot)$, solving the type-dependent value functions (6) or (7),
- all firms maximize their PDV of profits,
- the government does not violate its per-period budget constraint, levies taxes in accordance with its fiscal rule, and the price level is determined through equation (12),
- the central bank follows its policy rule (15),
- all markets clear ((18), (19a), (19b), equation (17) follows from Walras' Law), and
- the distribution of household wealth and productivity $\Gamma_t(B, b, z)$ evolves by its law of motion and is determined in the long-run by the fixed point of its evolution:

$$\Gamma_{t+1}(\mathcal{B}, \mathcal{b}, z') = \int_{\{(B, b, z): g_t(B, b, z) \in (\mathcal{B}, \mathcal{b})\}} \Pr(z'|z) d\Gamma_t(\mathcal{B}, \mathcal{b}, z).$$

We close the model by defining the utility function of consumption for each household i as $u(c) = \frac{c^{1-\sigma}-1}{1-\sigma}$, and the disutility function of labor supply as $v(N) = \frac{N^{1+\frac{1}{\varphi}}}{1+\frac{1}{\varphi}}$.

Steady-state: in the following, we will consider a log-linearized approximation around the deterministic steady-state with respect to aggregate variables. That steady-state will be characterized by a zero inflation rate, $\Pi = 1$, such that bond prices are equal to the household discount rate, $Q = \beta$ and $q = \beta$ in the absence of uncertainty. We furthermore normalize steady-state output to 1. The remainder of the steady-state will be characterized explicitly in line with the calibration introduced in section 6.

Steady-state determinacy with a simplified real interest rate determination

To provide a brief characterization supporting the possible uniqueness of the steady-state despite the high complexity of the model, we briefly invoke the framework of Hagedorn (2021) with an appropriate adjustment to include inflation-indexed debt, featuring the determination of the real interest rate with the help of asset market clearing.

We provide a general treatment of a possible equilibrium of the non-Ricardian economy with inflation-indexed debt and possibly heterogeneous agents, taking into account the ramifications that bond revaluations can have on asset markets in general equilibrium. Our proposal is that inflation-indexed debt can yield price level uniqueness in a stationary equilibrium if the real interest rate is determined *outside* the government budget equation (taking off the 'double burden' of determining both the initial price level P_0 and the real interest rate r_{ss} that this condition would alternatively be subject to), although some additional restrictions must be made. This statement is formalized in the following:

Proposition 3 (Stationary equilibrium determinacy in the sense of Hagedorn (2021)) *Under incomplete markets, with non-negative steady-state inflation, and abstracting from aggregate uncertainty, the*

intertemporal government budget equation can determine a unique initial price level in stationary equilibrium even in the presence of inflation-indexed debt for non-negative steady-state inflation rates if $\frac{b}{b+B} < 1$, $r_{ss} > 0$, and if a steady-state asset demand function $\Delta(r_{ss})$ exists and is invertible.

Proof. See appendix A.2. ■

Therefore, our model framework yields a unique initial price level in our setting with inflation-indexed debt, provided that the real interest rate is pinned down outside of the government budget valuation equation. The present result is, in a sense, a qualification of the results of Hagedorn (2021, 2024), applied suitably to a setting with inflation-indexed debt. This is done to ensure that we can operate with a clear, unique steady-state and analyze shocks to the economy without worrying about stationary equilibrium multiplicity.

The intuition behind the proof is the following: the intertemporal government budget equilibrium without inflation-indexed debt relates the price level to the real interest rate, which is determined on the asset market. With inflation-indexed debt, steady-state inflation itself becomes another element of the intertemporal government budget equilibrium. That inflation rate, which we posit to be pinned down by fiscal policy in the stationary equilibrium, is directly related to the real interest rate through the Fisher equation. Then, with the real interest rate (and implicitly inflation as well) being pinned down by asset market equilibrium, we only receive one plausible real interest rate that allows us to uniquely pin down the price level from the government budget constraint.

Equipped with our results on steady-state uniqueness in abstract general equilibrium models (that feature endogenous real interest rates, but do not take a stance how they arise), we are now moving on to describing the computational approach for our simulations with the help of the full-fledged general equilibrium model.

6 Calibration and computational approach

The parametrization of the economy used in the dynamic simulations is summarized by table 1. We follow overall the approach of Auclert et al. (2021), as we apply a conceptionally similar algorithm. In our preferred calibration, we vary government spending G and the household discount factor β to ensure that the goods market and the asset market for non-indexed clear. Finally, the market for inflation-indexed debt is targeted with the help of ν , the probability of being able to access the portfolio of indexed debt actively. These endogenous parameters are summarized by table 2. The market for non-indexed debt is not targeted, but clears with a tolerance of $1e-5$, while targeted market clearing conditions clear with close to machine precision ($1e-15$). To compare various policy combinations, we mostly restrict ourselves to baseline active/passive policy coefficients as given by Bianchi et al. (2023) within their NK-DSGE model. The parameters related to policy coefficients in the table below, $\{\phi_\pi, \phi_y, \gamma_B, \gamma_b\}$, should be taken as indicative and related to suitable active/passive policy combinations in the sense of Leeper (1991). When deviating from the baseline parameterizations mentioned in the table, we will explicitly introduce novel policy

coefficients as suitable.

Parameter.	Description	Value	Source/Target
<i>Firms</i>			
Y	Steady-state output	1	Normalization
ε	Elasticity of substitution between product varieties	3	Firm mark-up of 50%
κ	Slope of price Phillips curve	0.05	Conventional estimate
<i>Households</i>			
σ	Inverted intertemporal elasticity of substitution	1	Simplification for simulation
φ	Inverse Frisch elasticity of labor supply	1	Simplification for simulation
\underline{B}	Lower bound for non-indexed debt holdings	0	
\underline{b}	Lower bound for indexed debt holdings	0	
ρ_z	Persistence of AR(1) shocks to household productivity	0.966	Auclert et al. (2021)
σ_z	Standard deviation of AR(1) shocks to household productivity	0.92	Auclert et al. (2021)
<i>Government</i>			
T/G	Steady-state surplus, measured by the tax-to-government spending ratio	1.025	See explanation below
r^*	Natural rate of interest	0.015	Benigno et al. (2024)
ρ_M	Inertia in Taylor-type interest rate rule	0	Simplification
ϕ_π	Monetary policy reaction to inflation deviations from steady-state	{0.5, 1.5}	Bianchi et al. (2023)
ϕ_y	Monetary policy reaction to output deviations from steady-state	0	Bianchi et al. (2023)
γ_B	Fiscal policy reaction through non-indexed debt	{0.5, 1.5}	
γ_b	Fiscal policy reaction through indexed debt	{0.5, 1.5}	
B	Steady-state holdings of non-indexed debt	0.9	Non-indexed British sovereign debt relative to GDP
b	Steady-state holdings of non-indexed debt	0.22	Indexed British sovereign debt relative to GDP
<i>Simulation</i>			
n_z	Number of points in asset grid for household productivity shock	11	
n_b	Number of points in asset grid for indexed debt	50	
n_B	Number of points in asset grid for non-indexed debt	50	
\bar{B}	Maximum holdings of non-indexed debt in asset grid	5000	
\bar{b}	Maximum holdings of indexed debt in asset grid	5000	Approximation to Auclert et al. (2024)
T	Number of periods used in simulations of Jacobians	300	Auclert et al. (2021)

Table 1: Baseline parametrization for the quantitative estimation

Debt/GDP shares	HH discount factor	$\mathbb{P}(\text{adjustment})$	Govt. spending
$B: 0.85, b: 0.27$	<i>Main calibration: UK debt portfolio</i> $\beta = 0.9546$		$G = 0.3705$
$B: 1.0171, b: 0.1029$	<i>Counterfactual: US debt shares</i> $\beta = 0.9547$		$G = 0.3704$
$B: 1.12, b: 0.$	<i>Counterfactual: no indexed debt</i> $\beta = 0.9549$		$G = 0.3703$

Table 2: Endogenous parameters across different debt calibration scenarios

The calibration delivers overall reasonable estimates of the endogenous parameters that are in line with the parametrization of [Auclert et al. \(2021\)](#). The level of government spending is not targeted

to its empirical counterpart, yet the estimated government spending share is only slightly below the level of government spending in the UK prior to the pandemic (OBR, 2024b).

Finally, note that to pin down both the price level and the tax rate in steady-state, we exogenously fix the tax rate to be 2.5% higher than government spending in GDP, such that surpluses are equal to one percent of the government spending-to-GDP ratio. Note that this assumption runs counter to currently observed budget surpluses in the UK, which are decidedly negative. The proposed model, however, has issues in solving for perpetual deficits, conditional on the long-run real interest rate being positive.²⁴ However, the assumption of positive surpluses in steady-state remains qualitatively and quantitatively in line with some of the recent long-run forecasts of the current budget deficit provided by OBR (2024a) in their historical official forecasts database (table CB).²⁵

The entire steady-state is derived under the assumption of zero steady-state inflation, rendering limited relevance to the role of distorting inflation or interest rates different from the long-run natural rate. In terms of economic aggregates, the steady-state is thus well-described by the above calibration. Thanks to the normalization of output to unity and the calibrated share of government spending of 0.3705, we can deduce that consumption in steady-state will be equal to 0.6295 by market clearing, while taxation will be equal to 0.3815.

In terms of government debt, we will operate with and compare three different steady-state calibrations: one which follows the observed modal split of sovereign debt into non-indexed and indexed debt (such that $B = 0.85$ and $b = 0.27$), and two counterfactual calibrations where we either postulate a split between indexed and non-indexed debt as in the US (i.e., $B = 1.02$ and $b = 0.1$), or the complete absence of any indexed debt (i.e., $B = 1.12$ and $b = 0$), but maintaining in both cases the overall cumulative debt level observed in the UK. We therefore exogenously postulate the same steady-state bond supply across our calibrations, given that bond supply as a share of GDP is a relatively low-frequency variable, and given that the distribution of assets is an equilibrium outcome that depends on this supplied quantity. Many of our exercises will resolve around the differences between these calibrations, as we will mainly focus on the effect that indexed government debt has on economic aggregates.

Even though government debt aggregates are exogenously supplied in steady-state for all calibrations, the distribution of debt across households cannot be deduced immediately from the calibration itself, as it is generally dependent on the properties of the idiosyncratic process to income in a way that is not fully captured by the calibration itself. Figure 10 plots the distribution of debt holdings across households in two cases - once for the standard calibration to the UK, and one for the counterfactual calibration where steady-state issuance of indexed government debt is set to 0.²⁶

²⁴Kaplan et al. (2023) solve a model with negative surpluses and a negative steady-state real interest rate, but this is computationally difficult to implement for our chosen algorithm.

²⁵Conditional on a 40% share of government spending in GDP, the projected 1% budget surplus in the long-run as a share of GDP is equivalent to a ratio of sovereign income to spending of 1.025.

²⁶Note that the plot for the case without indexed debt shows some marginally non-zero holdings of indexed debt for a very small share of households. These are numerical inconsistencies, but even this counterfactual calibration still solves with a tolerance of $1e - 3$.

Note that the distribution of debt is by all means not a targeted moment, yet we can find, reassuringly, a significant skew in the distribution of debt holdings across simulated households. Given the larger presence of non-indexed sovereign debt, the holdings thereof are of course larger across the entire distribution, reflecting the evidence for the US provided in figure E.1 in the appendix.

Figure 10: Steady-state distributions of asset holdings across households in the calibrated steady-state

Computational details - using the Sequence-Space Jacobian:

The solution to the model that is linear in aggregates, but non-linear in idiosyncratic shocks, is derived by using the Sequence-Space Jacobian method developed in Auclert et al. (2021), which itself constitutes an evolution of the methods pioneered by Reiter (2009). The computational method we employ therefore generates perfect-foresight solutions in aggregates in response to time-zero perturbations of exogenous disturbances, but it maintains the non-linearity underlying the responses of heterogeneous households.

We first solve the heterogeneous household block, taking aggregate prices as given, for both the steady-state policy functions (through backwards iteration) and the steady-state distribution of asset holdings (through forwards iteration). Both solve with a numerical tolerance of up to $1e-7$, and are subsequently used to inform other blocks of the model (such as firm optimality, government policies, and market clearing) and to generate updates of aggregates where necessary. The two components (heterogeneous-agent and aggregate) interact and iterate until convergence, which is reached with a numerical threshold of $1e-6$ in the solution that is linear in aggregates, which is reasonable given the high degree of complexity underlying household behavior in the presence of two types of assets. The discretization of exogenous disturbances and the asset grid remain in line with the calibration of Auclert et al. (2021).

7 Quantitative insights from the HANK-Fiscal/Monetary Interactions-Fiscal Inflation model

With the computational algorithm at hand, we solve and estimate the model’s aggregate impulse-responses for a number of shocks, using the parametrization from table 1, but varying the calibration of the debt shares in line with table 2. Here, we will mostly focus on the effects of unanticipated disturbances to *government spending* G_t , which directly influence the surpluses raised by the government in any given period.²⁷

Before considering impulse-response functions in detail, we first look at the role that inflation-indexed debt plays for the amplification of shocks as evidenced through simulated moments, in line with the principal focus of the paper. To get a more detailed grasp behind that role borne by the presence of inflation-indexed debt for aggregates, we compare the simulated volatility of a number of macroeconomic aggregates across all calibrations (UK calibration, counterfactual US distribution of debt across the two types, and issuance of non-indexed debt only) and across both ‘standard’ policy combinations (passive monetary/active fiscal and active monetary/passive fiscal). The results of this exercise are presented in table 3.

	<i>Normalized standard deviations across policy scenarios</i>					
	PM/AF-UK	PM/AF-US split	PM/AF-NoIndex	AM/PF-UK	AM/PF-US split	AM/PF-NoIndex
G	1.527525	1.527525	1.527525	1.527525	1.527525	1.527525
Y	1.51838	1.565195	1.388928	1.291344	1.365381	1.277081
C	0.190974	0.248259	0.157339	0.381226	0.375627	0.440722
π	0.260869	0.236133	0.144924	0.177253	0.17356	0.151822
r	0.189807	0.202811	0.137661	0.237697	0.220391	0.22438
N	1.51838	1.565195	1.388928	1.291344	1.365381	1.277081

Table 3: Normalized standard deviations of aggregate variables in response to fiscal shocks with $\rho_G = 0.5$

The three left-hand columns can be summarized in one line and yield the main quantitative insight of the paper: the volatility of economic aggregates increases in the presence of inflation-indexed debt, conditional on being in the active fiscal policy case. Of particular interest in that regard is the fourth row of table 3, which captures the volatility of inflation in response to government spending shocks. Here, we can see that, conditional on being in the active fiscal policy scenario, the unweighted volatility of inflation is around 80% higher in the British sovereign debt case relative to the counterfactual without any inflation-indexed debt being present in response to government

²⁷Appendix B provides an overview of the dynamic responses to expansionary monetary policy shocks.

spending shocks. With a calibrated share of indexed sovereign debt of about 25%, we can therefore say that, on average, a one percentage point increase in the share of inflation-indexed debt more or less corresponds to an approximately 3% increase in the volatility of inflation in response to uncovered government spending shocks. Of course, this effect is far from linear, as evidenced by the second column which shows that the US calibration attains elevated levels of volatility, too, despite the share of indexed debt being only half of the UK share of indexed debt. To the best of our knowledge, we are among the first to quantitatively evaluate the impact that inflation-indexed debt can have on the volatility of inflation, and how such changes in volatility are directly related to the monetary-fiscal policy nexus, as the inflation volatility increase is evidently much smaller under the active monetary/passive fiscal scenario, amounting to a difference of only 17%.

We are now ready to look in more detail at the impulse responses to government spending shocks and the role borne by inflation-indexed debt when an unexpected government spending increase occurs. In general, we will allow for different possible autocorrelations of the fiscal shock to highlight the role of persistence and the forward-looking nature of the intertemporal government budget constraint as well. We begin by focusing on the case of *active fiscal policy* in line with the first parametrization introduced in table 2, i.e., the baseline calibration to the UK economy. Figure 11 plots IRFs of aggregate variables in response to a 100bp expansionary fiscal shock that increases the need for fiscal spending when the shock is highly persistent, i.e., $\rho_G = 0.8$.

Figure 11: IRFs to the government spending shock with active fiscal policy.

A number of observations is worth highlighting: the responses of consumption and tax rates are in line with canonical macroeconomic models and the expected reactions in response to the fiscal expansion: there is a corresponding increase in output (which partially crowds out consumption

as the fiscal shock itself is quite persistent) as the tax adjustment does *not* cover the additional expenses arising from the shock, in line with our specification of active fiscal policy. Notably, the tax rate deviation from steady-state is at first *negative*, highlighting that the real value of government bonds decreases below steady-state (which is related to the large negative real return shock that lowers the prices of bonds).

The response of aggregate inflation (and correspondingly of ex-post real interest rates) in the cases with positive levels of inflation-indexed debt confirms our analysis from the simplified model: while the fiscal expansion is related to inflationary pressure on impact, it translates to deflation in the medium-run before showcasing inflationary patterns in the longer-term. That medium-run slight deflationary pressure is relatively persistent. Across the specifications with positive levels of inflation-indexed debt, we therefore note that observed inflation rates exhibit the 'wave' pattern that we expected to arise through the presence of inflation-indexed debt and the dependence of the current price level on the future price level. Relative to the toy model discussed in section 3, the oscillations are more spread out here due to the relevance of production and household sectors in general equilibrium. In particular, the medium-term lack of price pressure is a direct consequence of the crowding out of household consumption due to the increase in government spending, which translates into temporarily lower inflation as households act under perfect foresight with respect to aggregate variables. Afterwards, as the government spending shock begins to die out, households push their consumption levels up, thereby leading to an increase in inflation rates that is accommodated by active fiscal policy that allows the devaluation of debt across time, with the persistence of this devaluation mechanism increasing in the share of inflation-indexed debt.

Turning off the debt indexation channel of government debt (i.e., setting inflation-indexed debt to zero) nullifies all dynamics beyond the first-order dynamics of the spending shock, allowing us to nest the standard expected reaction to a fiscal expansion in a world of active fiscal policy with non-Ricardian households: output and inflation comove, increasing above their respective steady-state values. Since we remain in a scenario of active fiscal policy, the government spending increase is not fully covered by a corresponding movement in taxation in that case either. The response of inflation is overall devoid of any persistence beyond the initial inflationary pressure from the shortfall of government income, and the response of the real interest rate is factually not persistent at all, since the real rate is perfectly forecastable after impact and is therefore taken into account by households. The magnitude of the response of tax rates is approximately a third of the response in the case with inflation-indexed debt, reflecting the decrease in the burden on taxation due to the absence of (costly) inflation-indexed debt.

An important factor in our above analysis is the persistence of the government spending shock, ρ_G . As the persistence of the shock underlying figure 11 is relatively high, the observed dynamics are tightly connected to intertemporal substitution motives for the household. To highlight the 'barebones' reaction of our economy to a one-off government spending shock (and to highlight the corresponding relevance of inflation-indexed debt in this world), we consider a non-persistent

fiscal shock next.

Figure 12: IRFs to the government spending shock with active fiscal policy - counterfactual without indexed debt.

Figure 12 summarizes the aggregate response of the economy to a fiscal spending shock when the government spending shock is not persistent at all, $\rho_G = 0$. Unsurprisingly, the persistence of output is virtually zero, too. As the government spending shock is short-lived, intertemporal substitution motives matter less, leading to less of a crowding out of consumption. Nonetheless, the fiscal authority of course continues to adjust the tax rate, where interesting differences between the cases of no indexed debt and strictly positive levels of indexed debt arise: while the tax rate returns to steady-state after two periods in the case without inflation-indexed debt (as should be expected), the tax rate shoots up more initially for the two scenarios with indexed debt, which is followed by a decrease of the tax rate below its steady-state, in line with the previously mentioned ‘overshooting’ of the devaluation of inflation-indexed debt. Interestingly, the differences between the UK calibration and the counterfactual with US debt shares are minuscule, reflecting the importance that the persistence of the shock has for the propagation of fiscal funding shortages.

Real rates correspondingly turn negative at the initial shock, followed by a gradual increase and a temporal positive deviation of real rates from their steady-state value. Inflation rates mirror this pattern in line with the Fisher equation (as the monetary authority remains passive), such that there is an uptick in inflation shortly on impact followed by a gradual unwinding relative to the observed steady-state of inflation. The volatility of inflation is generally one order of magnitude smaller relative to the case of persistent spending shocks, as expected.

Finally, we want to highlight what in our simulations changes when monetary policy turns *active*, while fiscal policy turns passive, in line with the calibration from table 1. Figure 13 summarizes the results from this exercise for highly persistent fiscal shocks, $\rho_G = 0.8$.

100bp govt. spending Shocks - AM/PF and $\rho = 0.8$

Figure 13: IRFs to the government spending shock with active monetary policy.

The responses of output and inflation turn out to be qualitatively similar *on impact* relative to the passive monetary policy case discussed above, while the reaction of tax rates differs markedly, as tax increases now cover the spending shock. This similarity in output and inflation across the calibrations will inform the discussion of the determinacy properties below. The change in output is larger on impact for the calibration to US debt shares as there is less crowding out of consumption relative to the UK calibration, while the inflationary impact is largest for the UK calibration.

After the initial impact from the unexpected shock, the response of inflation remains qualitatively similar across all three calibrations, i.e., irrespective of the share of debt that is indexed to inflation. This development is mirrored by qualitatively similar response of real interest rates present in the economy. This solidifies that inflation-indexed debt plays a role in particular when we have 'active' fiscal policy management in the sense of [Leeper \(1991\)](#), since in these situations the fiscal authority remains the prevailing driving force behind aggregate price changes.

The responses of output and tax rates show that these results are indeed driven mainly by the change in the policy mix, since the different calibrations induce varying observed impulse-responses after the initial period. Note that all this is true despite the economy being simulated in perfect-foresight after the initial shock. The fact that the fiscal expansion is met again with slight deflationary pressure further down the road in the cases with strictly positive levels of inflation-indexed debt reflects the interest rate-driven revaluation of government bonds that feeds back to changes in the price level through the intertemporal government budget equation.

Appendix [B](#) presents further omitted simulation results, in particular related to the IRFs of bond prices and interest rates, household policy functions and monetary policy shocks. In particular the revaluation of the bonds as expressed through their prices are of interest, as they confirm the above arguments that the revaluation of the intertemporal government budget equation belongs

to the main determinants of the inflationary response.²⁸

Impact responses of the price level depending on the share of inflation-indexed debt and the fiscal policy response

Having considered the general response of a battery of macroeconomic variables in response to surprise government spending shocks, we now zoom into the role borne jointly by inflation-indexed debt and the debt-related policy coefficients for inflation on impact of such shocks. To that goal, we fix the monetary policy coefficients at the levels summarized by table 1 and vary the share of inflation-indexed debt in the government debt portfolio, $\omega_t = \frac{b_t}{B_t + b_t}$, between $[0, 1]$ ²⁹, while also varying the strength of the fiscal policy reaction coefficients, $\{\gamma_B, \gamma_b\}$, between $[0, 1]$, which are the coefficients under which fiscal policy is conventionally considered "active". Note that we restrict ourselves to cases in which $\gamma_B = \gamma_b$ here, such that no variation of impact inflation is induced by a change of the *relative* prevalence of the two types of debt, as the share of inflation-indexed debt is kept at its respective calibrated steady-state value.³⁰

The first case that we consider is the one of conventionally passive monetary policy ($\phi_\pi = 0.5$). The impact reaction of the price level in this case is summarized by figure 14.

Figure 14: Impact reaction of prices in response to fiscal spending shocks under conventionally passive monetary policy.

On the x-axis, we vary the share of indexed debt in the total debt portfolio (while maintaining a constant overall relation between the gross stock of debt and GDP), while the colors indicate the chosen fiscal reaction coefficients $\gamma_B = \gamma_b$. Thus, orange and especially brown colors reflect 'less

²⁸In further work, we aim to quantify the effect of household heterogeneity more fully with the help of non-linear impulse-response functions that might showcase significant amplification of observed responses in labor supplied, output, and inflation for the case with inflation-indexed debt.

²⁹Recall that we cannot postulate all debt to be inflation-indexed in line with proposition 3.

³⁰Appendix figure B.8 provides evidence on the effects of variation of the fiscal policy reaction coefficients γ_b and γ_B for the impact reaction on the price level, keeping the overall stock of debt fixed at the 'UK Calibration' values.

active' fiscal policy in the conventional sense (as more of the shock is covered by corresponding tax raises), while greener colors reflect 'more active' fiscal policy.

We first focus on the leftmost point at which the share of inflation-indexed debt is exactly zero. There, we observe the conventional response that is expected in such models of fiscal-monetary interactions. The 'more active' fiscal policy is (i.e., as $\gamma_b, \gamma_B \rightarrow 0$), the stronger is the immediate impact on the price level when the shock occurs (the green lines are the highest for a zero share of inflation-indexed debt). This is fully in line with existing evidence from fiscal-monetary interaction models, and simply reflects that the necessary devaluation of a fully nominal debt stock is higher when income taxation does not react at all to the expansionary government spending shock. The difference across the various policy scenarios, however, is relatively small in this impact period.

The more interesting dynamics occur as we move to the right in the above picture, i.e., as we gradually increase the share of inflation-indexed debt in the government debt portfolio. We can broadly categorize the interaction between the adjustment coefficients and the share of indexed debt into two categories *based off the value of the adjustment coefficients of fiscal policy*:

- $\gamma_B = \gamma_b \gtrsim 0.3$ (orange-brown lines): Here, fiscal policy adjusts by covering comparatively more of the government spending shock through a corresponding increase in taxation. We observe uniformly that the higher the share of inflation-indexed debt, the greater is the change of the price level on impact, as the debt stock that can be devalued once the shock manifests itself is comparatively smaller, leading to a larger needed depreciation of that (smaller) stock of non-indexed debt.
- $\gamma_B = \gamma_b \lesssim 0.3$ (green lines): in these cases, the taxation schedule of the government covers only very little of the additional expense coming from the government spending shock. For realistic levels of inflation-indexed debt (below 40%), we can observe a general increase in the response of prices on impact, in line with standard predictions. The more indexed debt we have, the higher the devaluation of the outstanding debt stock must be, as in the case above. As the share of inflation-indexed debt becomes very large, however, we observe a surprising effect: the impact change of the price level actually starts to become smaller. This is directly related to the *real* side of the economy, as evidenced in figure 11: as the share of inflation-indexed debt increases, the real expansion of the economy becomes less pronounced, and the net worth of the wealthier households that hold large quantities of inflation-indexed debt decreases (as shown in figure B.6 in the appendix). This holds particularly true when the taxation reaction of the government is rather small. Through the Phillips Curve, then, we can observe downwards pressure on prices, overcoming some of the inflationary pressure induced through the government budget equilibrium.

Figure 15: Impact reaction of prices in response to fiscal spending shocks under conventionally active monetary policy.

Figure 15 repeats the above exercise, but for conventionally ‘active’ monetary policy with a reaction coefficient of $\phi_\pi = 1.5$. The principal results from the previous exercise under $\phi_\pi = 0.5$ translate to this case: while at zero inflation-indexed debt, the impact response of prices is larger under ‘more active’ fiscal policy scenarios, we again observe a widening of the responses as we increase the share of inflation-indexed debt and, except for the case of near-zero reaction coefficients, the degree to which the sovereign spending shock is inflationary is again increasing in the share of indexed debt. This effect remains particularly pronounced for reaction coefficients of around 0.5, i.e., when only half of the corresponding bond revaluation induced by the shock is covered by an increase in taxation, although the overall magnitudes are generally smaller relative to the case when monetary policy reacts less in terms of a possible interest rate adjustment.

Finally, I want to emphasize again that we are only considering the *impact* response of prices, not the cumulative response. This is an artifact of the idea that we are considering deviations from steady-state here, and with finite spending shocks, the model naturally will converge back to its steady-state at the old price level, as long as there is no permanent change in debt issuance. Further exercises with this model will therefore center on *permanently* increasing the issuance of either type of debt.

Fiscal-monetary policy combinations and determinacy

As a final exercise, we consider explicitly for which values of the fiscal and monetary policy parameters we can establish determinacy of the linearized system. In doing so, we exploit the ‘winding number criterion’ developed in Auclert et al. (2023), which is suitable given our choice of the sequence-space Jacobian as the primary device to solve the full dynamic model.³¹

³¹ A more detailed exposition of the ‘winding number criterion’ can be found in Auclert et al. (2023). Intuitively, one can relate this criterion to the Blanchard and Kahn (1980)-condition, which is cast in state-space. The winding number

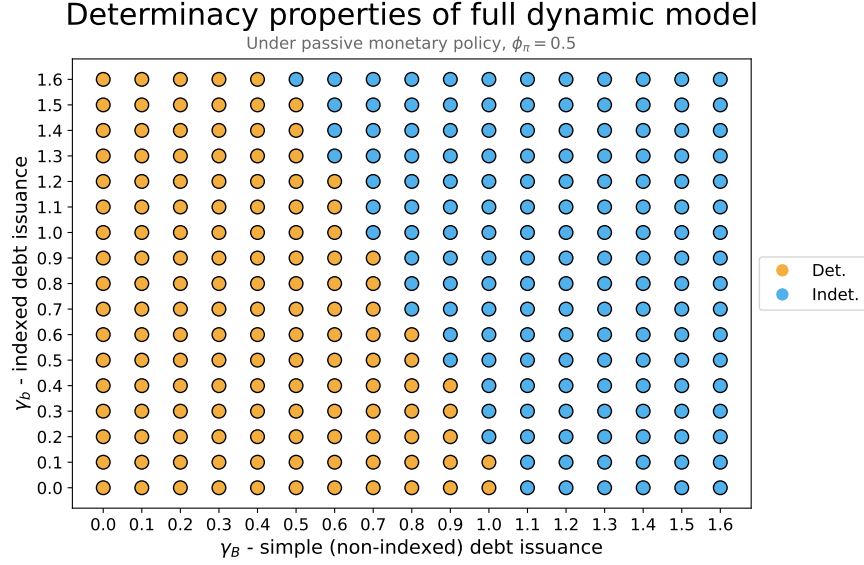

Figure 16: Determinacy of the generalized Jacobian in relation to choices for the fiscal and monetary policy reaction coefficients when monetary policy can be considered conventionally ‘passive’.

Figure 16 summarizes the determinacy properties of the model on an equispaced grid of the fiscal policy reaction parameters γ_B and γ_b , setting $\phi_\pi = 0.5$. We thus effectively say that monetary policy does *not* raise interest rates more than one-for-one with inflation, which is conventionally dubbed ‘passive monetary policy’. Interestingly, the results relate to canonical determinacy principles in line with [Leeper \(1991\)](#), even if they do not fully overlap. In particular, uniqueness of the equilibrium path is reached for conventional values of the non-indexed debt reaction parameter γ_B when inflation-indexed debt issuance in response to fiscal shocks is zero (which is evidenced by the last row of figure 16).

Once we allow the taxation schedule to be directly related to inflation-indexed debt deviations from equilibrium as well ($\gamma_b > 0$), two interesting phenomena arise. First, a trade-off in the government debt rule arises, by which an increased reactivity of the taxation schedule to deviations of the value of indexed debt b_t from steady-state must be paid off with a smaller reactivity with respect to the market value of non-indexed debt B_t . Second, this trade-off is non-linear: in particular, despite monetary policy being conventionally ‘passive’, it is possible for governments to react *more than one-for-one* ($\gamma_b > 1$) with their taxation schedule in relation to deviations of inflation-indexed debt from steady-state, provided that the adjustment with respect to non-indexed debt B_t is small enough. This is partially in line with our results from the analysis of a simplified Fisherian model in appendix C, to which we refer the interested reader for a closed-form analysis of determinacy properties with inflation-indexed debt in a simpler macroeconomic model.

criterion provides a generalizable ‘mapping’ of the Blanchard-Kahn conditions for the sequence-space, i.e., allowing infinitely many quasi-‘roots’ of the linearized system. Note that the prerequisites to apply the winding number criterion, such as the quasi-Toeplitz property of the generalized Jacobian, are not violated (the corresponding results are available upon request).

8 Discussion, summary, and next steps

This paper introduced inflation-indexed debt into models of the Fiscal Theory of the Price Level. We first provided support for the role of inflation-indexed debt as a major determinant of inflationary dynamics with the help of local projections applied to the UK and the US. Next, we established in a simplified model that such debt itself suffices to make the price level a backward-looking state variable: the previous price level therefore matters directly for the determination of today's price level. We followed up by a brief discussion of existing comparisons between fiscal dominance and other mechanisms inducing non-Ricardian household behavior, establishing that the inflation-indexed debt operates under mechanisms that are otherwise not existent in models with non-Ricardian mechanisms that abstain from an explicit fiscal block. Finally, we introduced inflation-indexed debt in a state-of-the-art macroeconomic model with imperfect markets and household heterogeneity, ensuring the existence of a unique steady-state before providing model-driven evidence that inflation-indexed debt can indeed exacerbate the inflationary response to government spending shocks, in particular when fiscal policy is considered conventionally 'active' in the sense of [Leeper \(1991\)](#).

Both the empirical and theoretical results derived in this paper thus tarnish the classic notion that inflation-indexed bonds always limit inflation in a given country by offering governments a commitment device to 'not inflate the debt away', as exposed in [Campbell and Shiller \(1996\)](#). While this notion can remain true absent government surplus shocks, our results point out that once the government budget is ex-post (after debt issuance) in disarray, the inflationary consequences of funding shortfalls can increase in the share of inflation-indexed debt. Issuance of indexed debt can therefore backfire despite its great ability to serve as an ex ante commitment device following [Schmid et al. \(2024\)](#).

Despite these conclusions, this project remains far from finished. In particular, the external validity of the results could be further strengthened by resorting to a more rigorous calibration to the UK economy. Another improvement to the paper could see a more thorough analysis of empirical drivers of net fiscal shocks (as developed in section 2) that overcomes the current limitations on the sample size, or determining the influence of the maturity structure of sovereign debt on observed inflationary dynamics. As [Cochrane \(2001\)](#) and [Barro and Bianchi \(2023\)](#) show, the maturity structure of government debt hugely matters for the trade-off between a front-loaded and a delayed inflation response to uncovered sovereign surplus shocks.

Finally, inflation-indexed debt can enhance our understanding in an important sphere of recent policy debates on the possible regressivity or progressivity of inflation as implicit taxation. As evidenced by figure E.1 in the appendix, inflation-indexed debt, which serves as a principal insurance device against unexpected inflation, seems to be particularly skewed in household portfolios towards the highest decile of the income distribution. A more thorough analysis of the welfare effects of unexpected inflation to households at varying income deciles should therefore be considered as a further policy-relevant application in due course.

Appendix

A Derivations and proofs from the main text

A.1 Derivations from section 5

Derivation of equation (12) (proof of proposition 2)

We here present the derivations underlying a *dynamic trading perspective* for asset valuation laid out in Brunnermeier et al. (2024), which avoids fallacies related to a possibly nonexistent aggregate transversality condition by clearly defining the valuation differences of government debt between households and the government based off the insurance properties that government bonds bear for households. This allows us to leverage household-level transversality conditions to derive an aggregate FTPL-type condition that only holds for one initial candidate price level.

The starting point for this valuation equation of government debt is the household budget constraint, which we recall was given by

$$P_t c_{it} + Q_t B_{it} + q_t b_{it} = \varepsilon_{it}(1 - \tau_{it})P_t w_t N_t + B_{i,t-1} + \Pi_t b_{i,t-1}$$

for each household i . Following our results derived in the household block, we let households price bonds in accordance with their SDF:

$$B_{i,t-1} + \Pi_t b_{i,t-1} = \mathbb{E}_t(M_{i,t,t+1}) B_{it} + \mathbb{E}_t(\Pi_{t+1} M_{i,t,t+1}) b_{it} + P_t(c_{it} - \varepsilon_{it} w_t N_t(1 - \tau_{it})).$$

Splitting up the second expectation term, we get

$$B_{i,t-1} + \Pi_t b_{i,t-1} = \mathbb{E}_t(M_{i,t,t+1}) B_{it} + \mathbb{E}_t(M_{i,t,t+1}) \mathbb{E}_t(\Pi_{t+1}) b_{it} + b_{it} \text{Cov}_t(M_{i,t,t+1}, \Pi_{t+1}) + P_t(c_{it} - \varepsilon_{it} w_t N_t(1 - \tau_{it})).$$

We divide all elements by P_t and add/subtract relevant terms on the right-hand side to ensure that we can iterate on the resulting expression:

$$\begin{aligned} \frac{B_{i,t-1} + \Pi_t b_{i,t-1}}{P_t} &= \mathbb{E}_t(M_{i,t,t+1}) \Pi_{t+1} \left[\frac{B_{it} + \Pi_{t+1} b_{it}}{P_{t+1}} \right] + (c_{it} - \varepsilon_{it}(1 - \tau_{it})w_t N_t) \\ &\quad + \text{Cov}_t(M_{i,t,t+1}, \Pi_{t+1}) \frac{b_{it}}{P_t} + \mathbb{E}_t(M_{i,t,t+1}) \frac{b_{it}}{P_t} (\mathbb{E}_t \Pi_{t+1} - \Pi_{t+1}). \end{aligned}$$

We can now start iterating on this expression. The first iteration yields:

$$\begin{aligned}
\frac{B_{i,t-1} + \Pi_t b_{i,t-1}}{P_t} &= \mathbb{E}_t (M_{i,t,t+1}) \Pi_{t+1} \left[\mathbb{E}_{t+1} (M_{i,t+1,t+2}) \Pi_{t+2} \left[\frac{B_{i,t+1} + \Pi_{t+2} b_{i,t+1}}{P_{t+2}} \right] \right. \\
&\quad \left. (c_{i,t+1} - \varepsilon_{i,t+1}(1 - \tau_{i,t+1})w_{t+1}N_{t+1}) + \text{Cov}_{t+1} (M_{i,t+1,t+2}, \Pi_{t+2}) \frac{b_{i,t+1}}{P_{t+1}} \right. \\
&\quad \left. + \mathbb{E}_{t+1} (M_{i,t+1,t+2}) \frac{b_{i,t+1}}{P_{t+1}} (\mathbb{E}_{t+1} \Pi_{t+2} - \Pi_{t+2}) \right] \\
&+ (c_{it} - \varepsilon_{it}(1 - \tau_{it})w_t N_t) + \text{Cov}_t (M_{i,t,t+1}, \Pi_{t+1}) \frac{b_{it}}{P_t} + \mathbb{E}_t (M_{i,t,t+1}) \frac{b_{it}}{P_t} (\mathbb{E}_t \Pi_{t+1} - \Pi_{t+1}).
\end{aligned}$$

Continuing rolling over, applying the LIE, and simplifying SDFs by making use of the identity $M_{i,t,t+k}M_{i,t+k,t+l} = M_{i,t,t+l} \forall t, k, l$, we eventually end up with:

$$\begin{aligned}
\frac{B_{i,t-1} + \Pi_t b_{i,t-1}}{P_t} &= \mathbb{E}_t \left[\sum_{k=0}^{\infty} M_{i,t,t+k} \Pi_{t+1,t+k+1} \left\{ (c_{i,t+k} - \varepsilon_{i,t+k}(1 - \tau_{i,t+k})w_{t+k}N_{t+k}) \right. \right. \\
&\quad \left. \left. + [\text{Cov}_{t+k} (M_{i,t+k,t+k+1}, \Pi_{t+k+1}) + M_{t+k,t+k+1} (\mathbb{E}_{t+k} \Pi_{t+k+1} - \Pi_{t+k+1})] \frac{b_{i,t+k}}{P_{t+k}} \right\} \right] \\
&\quad + \lim_{T \rightarrow \infty} \left\{ \mathbb{E}_t \left[M_{i,t,t+T} \left(\frac{B_{i,t+T} + \Pi_{t+T+1} b_{i,t+T}}{P_{t+T}} \right) \right] \right\}, \tag{A.1}
\end{aligned}$$

where we use the notation $\Pi_{t+1,t+k+1}$ to define gross inflation from period $t+1$ to period $t+k+1$. This is the integrated household budget constraint at optimality, from which we hope to derive the integrated government budget constraint.

Crucially, we note that household optimality implies $\lim_{T \rightarrow \infty} \frac{B_{i,T} + \Pi_{T+1} b_{i,T}}{P_T} \leq 0$, while a no-Ponzi condition on household debt holdings ensures that $\lim_{T \rightarrow \infty} \frac{B_{i,T} + \Pi_{T+1} b_{i,T}}{P_T} \geq 0$. Furthermore, by the definition of the SDF and the properties of a standard CRRA utility function, $\lim_{T \rightarrow \infty} M_{i,t,T} \neq \pm \infty$. Therefore, the final limit converges to 0 and must not be considered.³²

The formulation of equation (A.1) is intuitive: the real value of household bond holdings is equal to its expected discounted consumption benefits from today to infinity (as future net consumption earnings are suitably discounted with the SDF, which is a mirror image of the price of the two bonds), adjusted suitably for additional surprise earnings enjoyed from holdings of *indexed* sovereign debt: these are decreased by surprise inflation through its (negative) covariance with the SDF (as higher *future* inflation pushes the SDF down), and increased by surprise inflation through a level effect (since such inflation yields a windfall gain relative to what was paid for the indexed bond in the previous period).

We now aggregate these individual household bond constraints up to an integrated government budget constraint. We make use of the asset market clearing conditions $B_t = \sum_i B_{it}$ and $b_t = \sum_i b_{it}$ and of the idea that the household TVCs hold individually to get the following expression:

³²Even though this idea resembles the core idea behind Brunnermeier et al. (2020) and Brunnermeier et al. (2024), we are also overcoming the issues raised by Hagedorn (2024) by taking into account the dynamic trading (flow) benefits of government debt across time. This ensures the transversality conditions to hold for only one initial price level.

$$\begin{aligned} \frac{B_{t-1} + \Pi_t b_{t-1}}{P_t} = \sum_i \left\{ \mathbb{E}_t \left[\sum_{k=0}^{\infty} M_{i,t,t+k} \Pi_{t+1,t+k+1} \left\{ (c_{i,t+k} - \varepsilon_{i,t+k}(1 - \tau_{i,t+k}) w_{t+k} N_{t+k}) \right. \right. \right. \\ \left. \left. \left. + [Cov_{t+k}(M_{i,t+k,t+k+1}, \Pi_{t+k+1}) + M_{t+k,t+k+1}(\mathbb{E}_{t+k} \Pi_{t+k+1} - \Pi_{t+k+1})] \frac{b_{i,t+k}}{P_{t+k}} \right\} \right] \right\}. \end{aligned} \quad (\text{A.2})$$

We simplify this equation by noting that we can take the summation into the expectation and switch around the order of summation. To further simplify the integrated government budget valuation equation, we create the variable A_{it} which captures the surpluses raised by the government from each household i :

$$A_{it} \equiv c_{it} - \varepsilon_{it}(1 - \tau_{it}) w_t N_t + [Cov_t(M_{i,t,t+1}, \Pi_{t+1}) + M_{i,t,t+1}(\mathbb{E}_t \Pi_{t+1} - \Pi_{t+1})] \frac{b_{it}}{P_t},$$

which is the full portfolio return of household i of holding an additional unit of net worth. Alternatively, one can view this as what the government factually can raise as surpluses from each household i .

We additionally define $\bar{A}_t = \sum_i A_{it}$ as the sum of all individual-level surpluses. We can then rewrite the implied intertemporal government budget constraint (A.2) to:

$$\frac{B_t}{P_t} + \frac{b_{t-1}}{P_{t-1}} = \mathbb{E}_t \left[\sum_{k=0}^{\infty} \left(\sum_i M_{i,t,t+k} \Pi_{t,t+k+1} \frac{A_{i,t+k}}{\bar{A}_{t+k}} \right) \bar{A}_{t+k} \right],$$

or, defining the *household value-weighted SDF* $\tilde{M}_{t,t+k} = \sum_i M_{i,t,t+k} \Pi_{t,t+k+1} \frac{A_{i,t+k}}{\bar{A}_{t+k}}$, we finally arrive at:

$$\frac{B_t}{P_t} + \frac{b_{t-1}}{P_{t-1}} = \mathbb{E}_t \left[\sum_{k=0}^{\infty} \tilde{M}_{t,t+k} \bar{A}_{t+k} \right], \quad (\text{A.3})$$

where $\tilde{M}_{t,t+k}$ is now the weighted average SDF across all households i , adjusted for inflation, with weights being proportionate to $A_{i,t+k}$, consisting of the net utility gain from saving, the insurance premium on indexed debt (captured through the covariance term), and the possible windfall gain/loss from surprise inflation (captured through the last term in the definition of $A_{i,t+k}$). Equation (A.3) is 'the FTPL equation' that is used to pin down the price level at time t , given some previous price level P_{t-1} .

A.2 Proof of proposition 3

We first show that determinacy can indeed be achieved under an FTPL-type mechanism when indexed debt is present, provided that we include a suitable theory of the real interest rate, before showing how indexed debt translates into a model where taxation is assumed to cover all interest expenses over time on the stationary equilibrium path, following Hagedorn (2021). We therefore

maintain a 'true Balanced Growth Path' (BGP) with a constant real value of the debt portfolio thanks to an appropriate taxation schedule.

To apply the framework of [Hagedorn \(2021\)](#), we have to rewrite the steady-state taxation function to account for possible non-zero steady-state inflation and some positive level of indexed debt, since the presence of both changes the nominal value of taxation over time. We still aim to find an asset demand function depending only on model primitives.³³ To do so, we must pin down steady-state asset demand under incomplete markets in a closed-form solution, for which we will leverage the results of [Acemoglu and Jensen \(2015\)](#).

To find the steady-state level of taxation consistent with the bond issuance schedule that keeps the real value of bonds constant (provided that inflation devalues the non-indexed bonds), we begin with an arbitrary per-period government budget constraint (setting $G_t = 0$, such that real surpluses are $s_t = \tau_t$, or, in nominal terms, $P_t s_t = P_t \tau_t =: T_t$):

$$B_{t-1} + \frac{P_t}{P_{t-1}} b_{t-1} = T_t + Q_t B_t + q_t b_t.$$

Q_t and q_t must be equal to some constant values in steady-state. Without aggregate uncertainty, the bond prices arising through asset demand must solely depend on the offered interest rates, since cross-sectional risks average out. Thus, *in steady-state*, we have that:

$$\begin{aligned} B_{ss} + \Pi_{ss} b_{ss} &= T_{ss} + Q_{ss} B_{ss} + q_{ss} b_{ss} \\ \Leftrightarrow B_{ss} + \Pi_{ss} b_{ss} &= T_{ss} + \frac{1}{1+i_{ss}} B_{ss} + \frac{1}{1+r_{ss}} b_{ss} \\ \Leftrightarrow T_{ss} &= \left(1 - \frac{1}{1+i_{ss}}\right) B_{ss} + \left(\Pi_{ss} - \frac{1}{1+r_{ss}}\right) b_{ss}. \end{aligned}$$

Using the Fisher equation, we can see that $\Pi_{ss} - \frac{1}{1+r_{ss}} = \frac{1+i_{ss}}{1+r_{ss}} - \frac{1}{1+r_{ss}} = \frac{i_{ss}}{1+r_{ss}}$, and therefore:

$$T_{ss} = \frac{i_{ss}}{1+i_{ss}} B_{ss} + \frac{i_{ss}}{1+r_{ss}} b_{ss},$$

which can be expressed in real terms (as the household cares about real taxation) as

$$\tau_{ss} = \frac{r_{ss}}{1+i_{ss}} B_{ss} + \frac{r_{ss}}{1+r_{ss}} b_{ss}.$$

Define by $S_t(\Omega_t, \{1+r_t, \tau_t\}_t^\infty)$ the cumulative asset demand function under incomplete markets, which depends on the household distribution of wealth Ω_t , real interest rates $1+r_t$, and tax rates τ_t , and is well-defined under standard regularity conditions ([Acemoglu and Jensen, 2015](#)). To relate

³³For the sake of completeness, we want to specify the approach [Hagedorn \(2021\)](#) takes to determine steady-state taxation. He specifies the per-period government budget constraint as $B_{t+1} = (1+i_t)B_t - T_t \Leftrightarrow T_t = (1+i_t)B_t - B_{t+1}$ to arrive in steady-state at $T_{ss} = i_{ss} S_{ss}$, where S_{ss} is steady-state asset demand. in real terms, $\tau_{ss} =: \frac{T_{ss}}{P_{ss}} = r_{ss} S_{ss}$.

steady-state taxation more clearly to gross asset demand, we fix the shares of B_{ss} and b_{ss} of gross asset demand S_{ss} in steady-state. Denoting by ω the share of indexed debt b_{ss} in the steady-state asset portfolio, the taxation term in steady-state finally becomes

$$\tau_{ss} = \left[(1 - \omega) \frac{r_{ss}}{1 + i_{ss}} + \omega \frac{r_{ss}}{1 + r_{ss}} \right] S_{ss}.$$

Under such steady-state taxes, the gross asset demand function arising from heterogeneous household demand ($S_{t+1} = \mathcal{S}(\Omega_t; 1 + r_t, 1 + r_{t+1}, 1 + r_{t+2}, \dots; \tau_t, \tau_{t+1}, \dots)$) simplifies to the following mapping in steady-state:

$$S_{ss} = \mathcal{S} \left(\Omega_{ss}; 1 + r_{ss}, 1 + r_{ss}, 1 + r_{ss}, \dots; \left[(1 - \omega) \frac{r_{ss}}{1 + i_{ss}} + \omega \frac{r_{ss}}{1 + r_{ss}} \right] S_{ss}, \left[(1 - \omega) \frac{r_{ss}}{1 + i_{ss}} + \omega \frac{r_{ss}}{1 + r_{ss}} \right] S_{ss}, \dots \right).$$

With i_{ss} being equal to some constant set by the monetary policymaker in steady-state and the taxation function that we just derived, asset demand can again be derived by finding the fixed point of the above equation, which would yield asset demand as a function of the real interest rate r_{ss} , following [Acemoglu and Jensen \(2015\)](#):

$$\text{Asset demand: } S(r).$$

From our previous derivations, we directly leverage asset supply in real terms as the left-hand side of our derivations of the fiscal theory equation evaluated in steady-state, such that the stationary asset market equilibrium must be pinned down by

$$S(r) = \frac{B}{\tilde{P}} + \frac{b}{\tilde{P}(1 + \pi_{ss})},$$

or, making use of the Fisher equation,

$$S(r) = \frac{B}{\tilde{P}} + \frac{b(1 + r_{ss})}{\tilde{P}(1 + i_{ss})}.$$

An important question relates to the source of π_{ss} , the posited non-zero steady-state inflation rate in this economy. Following the contribution of [Hagedorn \(2021\)](#), we posit that the only possible non-zero steady-state inflation rate is the one consistent with a corresponding increase in taxation over time alongside this inflationary path:

$$1 + \pi_{ss} = \frac{T' - T}{T},$$

where variables with a prime denote next period values. Since T represents nominal taxes, the

above statement is equivalent to the claim that *real* taxes remain constant.

Given the bond portfolio on offer, we can express the above condition as follows:

$$1 + \pi_{ss} = (1 - \omega) \frac{B' - B}{B} + \omega \frac{b' - b}{b} \cdot (1 + \pi_{ss})$$

$$\Leftrightarrow 1 + \pi_{ss} = \frac{(1 - \omega) \frac{B' - B}{B}}{1 - \omega \frac{b' - b}{b}},$$

where the inflation-adjustment on the right-hand side in the first line follows from the adjustment of the face value of inflation-indexed debt. This bond issuance schedule therefore can be considered to pin down steady-state inflation.

Using the FTPL-style equation to determine the price level: We can now invoke the above derivations within the FTPL-style equation to pin down the price level uniquely, provided that we can recover the real interest rate from the asset market.

Following our above reasoning, that steady-state real interest rate can indeed be recovered from the asset market through household demand, provided that this demand function is invertible, as

$$r_{ss} = S^{-1} \left(\frac{B}{\tilde{P}} + \frac{b}{\tilde{P}(1 + \pi_{ss})} \right),$$

which we can insert in the stationary intertemporal FTPL equilibrium $\left(\frac{B}{\tilde{P}} + \frac{b}{\tilde{P}(1 + \pi_{ss})} = \sum_{j=0}^{\infty} \left(\frac{1}{1 + r_{ss}} \right)^j \bar{s} \right)$ with $r_{ss} > 0$ (such that the right-hand side can be rewritten as a geometric sum, $\sum_{j=0}^{\infty} \left(\frac{1}{1 + r_{ss}} \right)^j = \frac{1 + r_{ss}}{r_{ss}}$) to get the following condition:

$$\frac{B_{ss} + b_{ss}(1 + \pi_{ss})}{\tilde{P}} = \bar{s} \frac{1 + r_{ss}}{r_{ss}},$$

and the fixed point of this equation pins down the price level uniquely, given asset market optimality. To be precise, given our earlier definition of the surplus process, i.e., $\bar{s} = \tau_{ss} = \frac{r_{ss}}{1 + i_{ss}} B_{ss} + \frac{r_{ss}}{1 + r_{ss}} b_{ss}$, we have

$$\frac{B_{ss} + b_{ss}(1 + \pi_{ss})}{\tilde{P}} = \left[\frac{r_{ss}}{1 + i_{ss}} B_{ss} + \frac{r_{ss}}{1 + r_{ss}} b_{ss} \right] \frac{1 + r_{ss}}{r_{ss}}.$$

Using the Fisher equation $((1 + i_{ss}) = (1 + r_{ss})(1 + \pi_{ss}))$, we can simplify this equilibrium relation to:

$$\frac{B_{ss}}{\tilde{P}} + \frac{b}{\tilde{P}(1 + \pi_{ss})} = (1 + \pi_{ss})B + b,$$

which eventually pins down the price level as

$$\tilde{P} = \frac{B_{ss} + b_{ss}(1 + \pi_{ss})}{(1 + \pi_{ss})B_{ss} + b_{ss}}.$$

From the taxation schedule (which is a fiscal variable itself, actively managed by fiscal policy), we can recover the steady-state inflation rate. We simplify this by utilizing the steady-state growth rates $\frac{B'-B}{B} =: g_B$ and $\frac{b'-b}{b} =: g_b$, such that steady-state inflation becomes $1 + \pi_{ss} = \frac{(1-\omega)\frac{B'-B}{B}}{1-\omega\frac{b'-b}{b}} = \frac{(1-\omega)g_B}{1-\omega g_b}$. Thus, the initial price level in this steady-state is given by:

$$\tilde{P} = \frac{B_{ss} + b_{ss} \frac{(1-\omega)g_B}{1-\omega g_b}}{B_{ss} \frac{(1-\omega)g_B}{1-\omega g_b} + b_{ss}},$$

with the bond growth rates themselves being fiscal choice variables in the stationary equilibrium.

B Further simulation results

Figure B.1: Household policy functions for demand of non-indexed debt in the calibrated HANK model for unconstrained households. Note that the policy functions for low values of idiosyncratic productivity start to become positive only for strictly positive levels of non-indexed debt due to the possibility to purchase inflation-indexed debt stock.

Next, this appendix showcases dynamic impulse-responses of aggregate variables in response to a 25bps expansionary monetary policy shock, as well as the results of a full non-linear estimation of the model, which encountered significant numerical instabilities.

25 bp monetary policy shocks - PM/AF and $\rho = 0.8$

Figure B.2: IRFs to a 25bps expansionary monetary shock - with active fiscal policy and $\rho = 0.8$.

25 bp monetary policy shocks - PM/AF and $\rho = 0.0$

Figure B.3: IRFs to a 25bps expansionary monetary shock - with active fiscal policy and $\rho = 0$.

25 bp monetary policy shocks - AM/PF and $\rho = 0.8$

Figure B.4: IRFs to a 25bps expansionary monetary shock - with active monetary policy and $\rho = 0.8$.

25 bp monetary policy shocks - AM/PF and $\rho = 0.0$

Figure B.5: IRFs to a 25bps expansionary monetary shock - with active monetary policy and $\rho = 0$.

For our main policy scenario ('passive monetary policy' and 'active fiscal policy'), we furthermore provide additional evidence on changes of quantities directly informing the core FTPL equation (12).

Figure B.8: Impact reaction of prices in response to fiscal spending shocks under conventionally passive monetary policy in the UK calibration, depending on the reaction coefficients of fiscal policy γ_b and γ_B . The black dotted line summarizes impact responses of prices when $\gamma_b + \gamma_B = 1$.

C Fiscal rules and inflation-indexed debt: an example from a Fisherian model

To illustrate simply how indexed debt enters a canonical macroeconomic model in general equilibrium, we consider here a Fisherian economy with a representative household saving in the two types of government bonds available. We do so to analyze how the presence of indexed debt can influence equilibrium properties in dynamic economies, as this will be an important consideration in the final dynamic model. In the toy model that we lay out here, a representative household receives a constant stream of goods Y , solving

$$\max_{\{c_t, B_t, b_t\}_{t=0}^{\infty}} \mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t u(c_t),$$

subject to the flow budget constraint

$$P_t c_t + Q_t B_t + q_t b_t = P_t (Y - T_t) + B_{t-1} + \Pi_t b_{t-1},$$

where B_t and b_t denote nominal quantities of non-indexed and inflation-indexed debt, respectively, such that the face value payment of indexed debt b_{t-1} is scaled by the level of gross inflation Π_t . T_t here denotes gross lump-sum taxes raised by the government on the income stream enjoyed by the household. The household optimality conditions are given by

$$\begin{aligned}
\{c_t\} : \quad & u'(c_t) = \lambda_t P_t \\
\{B_t\} : \quad & \lambda_t Q_t = \beta \mathbb{E}_t \lambda_{t+1} \\
\{b_t\} : \quad & \lambda_t q_t = \beta \mathbb{E}_t \lambda_{t+1} \Pi_{t+1}.
\end{aligned}$$

Using market clearing $c_t = Y \forall t$, we obtain standard bond pricing kernels:

$$Q_t = \beta \mathbb{E}_t \left(\frac{P_t}{P_{t+1}} \right); \quad q_t = \beta,$$

reflecting that inflation-indexed bonds are completely risk-free in a world of representative households and perfect credit markets.

Government: The simple flow budget constraint of the government is given by

$$B_{t-1} + \Pi_t b_{t-1} = P_t T_t + Q_t B_t + q_t b_t,$$

with the bond pricing kernels being given by the household first-order conditions. For simplicity, we assume here that $s_t = T_t$, i.e., we abstain from government spending without loss of generality.

Under this simple setting, a standard fiscal policy rule in a Fisherian model sees a government react to deviations of both types of debt in *real* terms from their respective steady-state levels:

$$\frac{\tau_t}{\tau} = \left(\frac{s_{B,t-1}}{s_B} \right)^{\gamma_B} \left(\frac{s_{b,t-1}}{s_b} \right)^{\gamma_b} e^{\zeta_t},$$

where $\tau_t \equiv \frac{T_t}{Y}$ are surpluses raised by the government as a fraction of output, and $s_{B,t} \equiv \frac{Q_t B_t}{P_t Y}$, $s_{b,t} \equiv \frac{q_t b_t}{P_t Y}$ are the real market values of the two existing types of debt. ζ_t is a standard AR(1) shock to the quantity of lump-sum taxes raised, and the policy reaction coefficients are given by γ_B and γ_b .

The central bank follows a simplified monetary rule for maximum analytical tractability:

$$\frac{R_{n,t}}{R_n} = \left(\frac{\Pi_t}{\Pi} \right)^\phi,$$

where $R_{n,t} = 1 + i_t$ is the gross nominal interest rate. Note also that under the present setting $Q_t = \frac{1}{R_{n,t}}$, i.e., the price of the nominal bond must be the inverse of the gross nominal interest rate.

Linearizing the simple Fisherian model: we denote variables in their log-deviations from steady-state with hats. A simple (log)-linearization around the zero-inflation steady-state gives us the following system of equations:

- Nominal bond prices: using $Q_t = \frac{1}{R_{n,t}}$ and $Q_t = \beta \mathbb{E}_t \left(\frac{1}{\Pi_{t+1}} \right)$, we get $\frac{1}{R_{n,t}} = \beta \mathbb{E}_t \left(\frac{1}{\Pi_{t+1}} \right)$. To a first-order approximation,

$$\hat{r}_{n,t} = \mathbb{E}_t \hat{\pi}_{t+1}. \quad (\text{C.4})$$

- Monetary rule: taking simply logs of the monetary rule, we get

$$\hat{r}_{n,t} = \phi \hat{\pi}_t. \quad (\text{C.5})$$

- Law of motion of debt: we take the law of motion of debt, divide it by $(P_t Y)$, and apply the debt share definitions from above:

$$\begin{aligned} \frac{Q_t B_t}{P_t Y} + \frac{q_t b_t}{P_t Y} + \frac{T_t}{Y} &= \frac{Q_{t-1} B_{t-1}}{P_{t-1} Y} \frac{1}{Q_{t-1}} \frac{P_{t-1}}{P_t} + \frac{q_{t-1} b_{t-1}}{P_{t-1} Y} \frac{1}{q_{t-1}} \Pi_t \frac{1}{\Pi_t} \\ &\Leftrightarrow s_{B,t} + s_{b,t} + \tau_t = s_{B,t-1} R_{n,t-1} \frac{1}{\Pi_t} + s_{b,t-1} \frac{1}{\beta}. \end{aligned}$$

This expression cannot be log-linearized exactly, but we can obtain a first-order Taylor approximation:

$$\begin{aligned} &s_B + s_b + \tau + (s_{B,t} - s_B) + (s_{b,t} - s_b) + (\tau_t - \tau) \\ &= s_B R_n \frac{1}{\Pi} + s_b \frac{1}{\beta} + \frac{R_n}{\Pi} (s_{B,t-1} - s_B) + \frac{s_B}{\Pi} (R_{n,t-1} - R_n) - \frac{s_B R_n}{\Pi^2} (\Pi_t - \Pi) + \frac{1}{\beta} (s_{b,t-1} - s_b). \end{aligned}$$

Getting rid of the steady-state, using $\Pi = 1$ and $R_n = \frac{1}{\beta}$, and dividing all elements by s_B , we obtain:

$$\hat{s}_{B,t} + \frac{s_b}{s_B} \hat{s}_{b,t} + \frac{\tau}{s_B} \hat{\tau}_t = \frac{1}{\beta} \left[\hat{s}_{B,t-1} + \hat{r}_{n,t-1} - \hat{\pi}_t + \frac{s_b}{s_B} \hat{s}_{b,t-1} \right].$$

Now, in steady-state, $\bar{Q} = \bar{q} = \beta$. Thus, $\frac{s_b}{s_B} = \frac{b}{B}$. Also, from the flow budget constraint evaluated at steady-state, we know that $PT = (1 - \beta)(B + b)$, such that the steady-state taxation term can be rewritten as $\frac{\tau}{s_B} = \frac{\tau PY}{QB} = \frac{1}{\beta} \frac{TP}{B} = \frac{1-\beta}{\beta} \left(\frac{B+b}{B} \right)$. Combining these elements, we finally obtain the linearized budget constraint:

$$\hat{s}_{B,t} + \frac{b}{B} \hat{s}_{b,t} = \frac{1}{\beta} \left[\hat{s}_{B,t-1} + \hat{r}_{n,t-1} - \hat{\pi}_t + \frac{b}{B} \hat{s}_{b,t-1} - (1 - \beta) \frac{B+b}{B} \hat{\tau}_t \right]. \quad (\text{C.6})$$

- Fiscal rule: the fiscal rule can be log-linearized exactly:

$$\hat{\tau}_t = \gamma_B \hat{s}_{B,t-1} + \gamma_b \hat{s}_{b,t-1} + \zeta_t. \quad (\text{C.7})$$

We can combine equations (C.4)+(C.5) and (C.6)+(C.7), respectively, to attain the following system of difference equations:

$$\mathbb{E}_t \hat{\pi}_{t+1} = \phi \hat{\pi}_t, \quad (\text{C.8})$$

$$\hat{s}_{B,t} + \frac{b}{B} \hat{s}_{b,t} = \frac{1}{\beta} \left[\hat{s}_{B,t-1} + \frac{b}{B} \hat{s}_{b,t-1} \right] + \frac{1}{\beta} \left[\hat{r}_{n,t-1} - \hat{\pi}_t - (1-\beta) \frac{B+b}{B} \zeta_t \right] - \frac{1-\beta}{\beta} \frac{B+b}{B} [\gamma_B \hat{s}_{B,t-1} + \gamma_b \hat{s}_{b,t-1}]. \quad (\text{C.9})$$

The presence of indexed debt introduces a third first-differenced variable into this policy-side system of equations, \hat{s}_b . We therefore need to close this system with some further condition.³⁴

The first idea is a straightforward *simplification* of the problem by imposing the following relationship in terms of the debt issuance between the two types of debt offered: $\gamma_b = \frac{b}{B} \gamma_B$, such that the issuance of the two types of debt is proportional to their relative share of overall outstanding debt in steady-state. The resulting log-linearized 'fiscal' equation can then be expressed as:

$$\hat{s}_{B,t} + \frac{b}{B} \hat{s}_{b,t} = \frac{1}{\beta} \left[1 - (1-\beta) \frac{B+b}{B} \gamma_B \right] \left[\hat{s}_{B,t-1} + \frac{b}{B} \hat{s}_{b,t-1} \right] + \frac{1}{\beta} \left[\hat{r}_{n,t-1} - \hat{\pi}_t - (1-\beta) \frac{B+b}{B} \zeta_t \right].$$

Under this set-up, we can define the novel state variable $\hat{s}_{D,t}$, where D stands for the "total debt stock", such that $\hat{s}_{D,t} \equiv \hat{s}_{B,t} + \frac{b}{B} \hat{s}_{b,t}$.

$$\hat{s}_{D,t} = \frac{1}{\beta} \left[1 - (1-\beta) \frac{B+b}{B} \gamma_B \right] \hat{s}_{D,t-1} + \frac{1}{\beta} \left[\hat{r}_{n,t-1} - \hat{\pi}_t - (1-\beta) \frac{B+b}{B} \zeta_t \right]. \quad (\text{C.10})$$

Together with equation (C.8), we get the following system of equations:³⁵

$$\underbrace{\begin{bmatrix} 1 & 0 \\ \frac{1}{\beta} & 1 \end{bmatrix}}_{A_0} \mathbb{E}_t \begin{bmatrix} \hat{\pi}_{t+1} \\ \hat{s}_{D,t+1} \end{bmatrix} = \underbrace{\begin{bmatrix} \phi & 0 \\ 0 & \frac{1}{\beta} \left[1 - (1-\beta) \frac{B+b}{B} \gamma_B \right] \end{bmatrix}}_{A_1} \begin{bmatrix} \hat{\pi}_t \\ \hat{s}_{D,t} \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{1}{\beta} \left[\hat{r}_{n,t-1} - (1-\beta) \frac{B+b}{B} \zeta_t \right] \end{bmatrix}$$

Note that $A_0^{-1} = \begin{bmatrix} 1 & -\frac{1}{\beta} \\ 0 & 1 \end{bmatrix}$. We are interested in the determinacy properties of the matrix

$$Z \equiv A_0^{-1} A_1 = \begin{bmatrix} 1 & -\frac{1}{\beta} \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \phi & 0 \\ 0 & \frac{1}{\beta} \left[1 - (1-\beta) \frac{B+b}{B} \gamma_B \right] \end{bmatrix} = \begin{bmatrix} \phi & -\frac{1}{\beta} \frac{1}{\beta} \left[1 - (1-\beta) \frac{B+b}{B} \gamma_B \right] \\ 0 & \frac{1}{\beta} \left[1 - (1-\beta) \frac{B+b}{B} \gamma_B \right] \end{bmatrix}.$$

The eigenvalues of Z are given by

$$\left\{ \phi, \quad \frac{1}{\beta} \left[1 - (1-\beta) \frac{B+b}{B} \gamma_B \right] \right\}.$$

³⁴We restrict all policy reaction parameters to be *non-negative* for expositional simplicity: $\phi \geq 0, \gamma_B \geq 0, \gamma_b \geq 0$.

³⁵Note that we move equation (C.10) one period forwards for the first-differenced system, so π_t appears on the LHS.

Following [Blanchard and Kahn \(1980\)](#), saddle-path stability of this system requires one eigenvalue inside and one outside the unit circle. We thus have saddle-path stability under the following policy combinations:

- "Active monetary/passive fiscal": $\phi > 1$ & $\gamma_B > \frac{B}{B+b}$,
- "Passive monetary/active fiscal": $\phi < 1$ & $\gamma_B < \frac{B}{B+b}$,

such that the restriction to pursue active fiscal policy is *tighter* relative to the result established in [Leeper \(1991\)](#). Intuitively, 'fiscal activism' now requires the fiscal reaction coefficient to be sufficiently far away from unity, since 'almost passive' fiscal reactions might *actually* yield passive fiscal authorities due to the debt stock not being sufficiently devalued for a stable path of the price level. The fact that the local determinacy bounds are nonetheless relatively similar to [Leeper \(1991\)](#) is a consequence of ensuring that the share of indexed debt is *constant* in the face of tax shocks.³⁶ Because of that simplification, ensuring determinacy in the 'active fiscal'-world simply requires the tax schedule to raise enough surpluses to ensure no 'devaluation spiral', which would be induced by *not* raising sufficient surpluses to cover the higher face value payment coming from inflation-indexed debt when surprise inflation materializes.

—

The other possible approach to close the economy is the 'shadow economy' trick used by [Bianchi et al. \(2023\)](#). Following [Bianchi et al. \(2023\)](#), we construct a 'shadow economy' that has the same monetary block, but a simplified fiscal block with *only* non-indexed debt: $b_t = 0 \forall t$. The underlying assumption behind this 'shadow economy' is tantamount to postulating that the fiscal authority *only* reacts with non-indexed debt in response to fiscal disturbances: when a spending shortage or surplus occurs, the fiscal authority only reacts by adjusting the stock of non-indexed debt.³⁷ This simplified fiscal block is summarized by the log-linearized equation

$$\hat{s}_{B,t} = \frac{1}{\beta} [1 - (1 - \beta)\gamma_B] \hat{s}_{B,t-1} + \frac{1}{\beta} [\hat{r}_{n,t-1} - \hat{\pi}_t - (1 - \beta)\zeta_t], \quad (\text{C.11})$$

which is the standard Fisherian model with non-indexed debt only. Combining equations (C.8), (C.9), and (C.11), we obtain the following system of linear difference equations:

$$\underbrace{\begin{bmatrix} 1 & 0 & 0 \\ \frac{1}{\beta} & \frac{b}{B} & 1 \\ \frac{1}{\beta} & 0 & 1 \end{bmatrix}}_{=A_0} \mathbb{E}_t \begin{bmatrix} \hat{\pi}_{t+1} \\ \hat{s}_{b,t+1} \\ \hat{s}_{B,t+1} \end{bmatrix} = \underbrace{\begin{bmatrix} \phi & 0 & 0 \\ 0 & \frac{1}{\beta} \left[\frac{b}{B} - (1 - \beta)\frac{B+b}{B}\gamma_B \right] & \frac{1}{\beta} \left[1 - (1 - \beta)\frac{B+b}{B}\gamma_B \right] \\ 0 & 0 & \frac{1}{\beta} [1 - (1 - \beta)\gamma_B] \end{bmatrix}}_{=A_1} \begin{bmatrix} \hat{\pi}_t \\ \hat{s}_{b,t} \\ \hat{s}_{B,t} \end{bmatrix} + C \begin{bmatrix} \hat{r}_{n,t} \\ \zeta_t \end{bmatrix}$$

The determinacy properties of this system again depend on $Z \equiv A_0^{-1}A_1$. This matrix Z is given by:

³⁶This is ensured by $\gamma_b = \frac{b}{B}\gamma_B$.

³⁷Following [Bianchi et al. \(2023\)](#), an otherwise more common example related to standard monetary economics are 'shadow economies' used to close models with price rigidities, in which the 'shadow economy' is one with flexible prices and no inefficient shocks.

$$Z = \begin{bmatrix} \phi & 0 & 0 \\ 0 & \frac{1}{\beta} \left[1 - (1 - \beta) \frac{B+b}{b} \gamma_b \right] & -\frac{1-\beta}{\beta} \gamma_B \\ -\frac{\phi}{\beta} & 0 & \frac{1}{\beta} \left[1 - (1 - \beta) \gamma_B \right] \end{bmatrix}$$

with corresponding eigenvalues

$$\left\{ \phi, \frac{1}{\beta} \left[1 - (1 - \beta) \gamma_B \right], \frac{1}{\beta} \left[1 - (1 - \beta) \frac{B+b}{b} \gamma_b \right] \right\},$$

and since the system consists of one forward-looking and two backward-looking variables, we now need one eigenvalue outside the unit circle in modulus and two inside to ensure determinacy. Relevant policy mixes inducing saddle-path stability are thus given by:³⁸

- *AM/PF*: $\phi > 1, \gamma_B > 1, \gamma_b > \frac{b}{B+b}$;
- *PM/AF_B/PF_b*: $\phi < 1, \gamma_B < 1, \gamma_b > \frac{b}{B+b}$;
- *PM/AF_B/PF_b*: $\phi < 1, \gamma_B > 1, \gamma_b < \frac{b}{B+b}$,

such that active fiscal policy can choose what type of debt to actively take on in response to fiscal shocks. For better intuition, it is instructive to consider two specific types of debt policies:

- $\gamma_b = \gamma_B \frac{b}{B+b}$: under such a debt issuance rule, there are only two distinct eigenvalues, similar to the case above due to the induced co-movement of both types of debt in response to deviations from steady-state.
- $\gamma_b = \gamma_B$: such a fiscal rule would indicate a fiscal authority reacting with similarly-sized deviations of both types of debt from their respective steady-state values in response to shocks to the revenue generated by taxation. In that case, we recover the eigenvalues

$$\left\{ \phi, \frac{1}{\beta} \left[1 - (1 - \beta) \gamma_B \right], \frac{1}{\beta} \left[1 - (1 - \beta) \frac{B+b}{b} \gamma_B \right] \right\}, \quad (\text{C.12})$$

depending on one fiscal policy reaction parameter and one monetary policy reaction parameter only. Policy combinations supporting saddle-path stability are then given by:

- *AM/PF*: $\phi > 1, \gamma_B > 1, \gamma_b > \frac{b}{B+b}$;
- *PM/AF-1*: $\phi < 1, \gamma_B > 1, \gamma_b < \frac{b}{B+b}$;
- *PM/AF-2*: $\phi < 1, \gamma_B < 1, \gamma_b > \frac{b}{B+b}$.

Note that case *PM/AF-1* is not possible, so the only viable active fiscal policy combination here is *PM/AF-2*. Clearly, relative to a standard [Leeper \(1991\)](#)-model, it implies tighter bounds, ruling out 'fully active' fiscal policies of the type $\gamma_B = 0$ so long as $b > 0$: fiscal pol-

³⁸In the following list, "A" refers to *active*, "P" refers to *passive* (in the sense of [Leeper \(1991\)](#)), "M" refers to *monetary*, and "F" refers to *fiscal* policies. Additionally, fiscal policies are subscripted with non-indexed ("B") and indexed ("b") debt.

icy therefore cannot be ‘fully active’ in the traditional sense, as such behavior would mean an unbounded devaluation of the debt stock as not enough surpluses are raised to service the spiraling costs of indexed debt.

This Fisherian model therefore established that indexed debt can greatly influence the conduct of ‘active’ fiscal policy in the sense of [Leeper \(1991\)](#): in particular, the conditions for active saddle-path stable fiscal policy are unequivocally tightened across all our examples for specific policy rule combinations. While these insights rationalize the importance of indexed debt for determinacy properties of dynamic economic models, the implications of this simple model need not directly translate to state-of-the-art dynamic macroeconomic models.

D [Angeletos et al. \(2024\)](#) with inflation-indexed debt

Instead of laying out the cases of fiscal dominance under RANK and monetary dominance under HANK separately as done in [Angeletos et al. \(2024\)](#), we analyze both cases jointly as a dynamic system, keeping the parametrization of fiscal policy, monetary policy, and the mortality friction opaque for as long as possible. This is done to minimize the length of the analysis, and, given that we limit us to proving that inflation-indexed debt induces a wedge between the RANK and HANK cases in the limit point where fiscal and monetary dominance collapse, this joint analysis does not limit the scope of our results.

We now re-develop the model of [Angeletos et al. \(2024\)](#), which is an OLG-NK model in the spirit of [Blanchard \(1985\)](#). The idea is that the mortality friction can be considered a proxy for liquidity risk commonplace in canonical HANK models while maintaining superior tractability properties.

In the following section, uppercase variables define the level values of variables, while lowercase variables are log-deviations from steady-state. The steady-state will be log-linearized around zero inflation ($\Pi^{SS} = 1$), and the fiscal variables debt (d_t), taxes (t_t), and assets (a_t) will all be measured in *absolute* deviations from steady-state (not log deviations) to ensure that zero-debt steady-states are not excluded.

D.1 Household block

The probability of surviving from one period to another is captured by $\omega \in (0, 1]$. Households are replaced by new ones whenever they die. They maximize expected utility, given by

$$\mathbb{E}_t \left[\sum_{k=0}^{\infty} (\beta\omega)^k \left[\frac{C_t^{1-\frac{1}{\sigma}} - 1}{1 - \frac{1}{\sigma}} - \nu \frac{L_t^{1+\frac{1}{\phi}}}{1 + \frac{1}{\phi}} \right] \right]. \quad (\text{D.13})$$

The household budget constraint: to retain the tractability behind the original analysis of [Angeletos et al. \(2024\)](#), we too posit that households can trade in a risk-free annuity, earning a specified nominal rate of return R_t^P . That annuity consists of a representative share of the government debt portfolio, which consists of regular debt B_t^R earning a gross return I_t , where I_t is the gross nom-

inal interest rate, and *inflation-indexed debt* B_t^I , which earns a gross rate of return $I_t \frac{P_{t+1}}{P_t}$, reflecting the face value adjustment of such debt. The gross portfolio return of the household consists of a weighted average of the returns earned by the two individual asset classes, where we specify the constant share of inflation-indexed debt in the government bond portfolio as θ :

$$R_t^P = \theta I_t \frac{P_{t+1}}{P_t} + (1 - \theta) I_t = I_t \left(1 + \theta \left(\frac{P_{t+1}}{P_t} \right) \right), \quad (\text{D.14})$$

which captures the pre-death probability rate of return on the portfolio of government debt owned as the only savings asset by each household. The remainder of the budget constraint follows [Angeletos et al. \(2024\)](#) closely: all households receive labor income and dividends $W_t L_{it} + Q_{it}$, are taxed in accordance with a taxation rule, and all old households make a contribution S_{it} to a social fund whose proceeds are distributed to newborn households, eliminating wealth effects from mortality risk.³⁹ The household-specific budget constraint is then given by:

$$P_{t+1} A_{i,t+1} = \frac{R_t^P}{\omega} P_t \left(A_{it} + \underbrace{Y_{it}}_{\equiv W_t L_{it} + Q_{it}} - C_{it} - T_{it} + S_{it} \right). \quad (\text{D.15})$$

We retain all other household-side assumptions from [Angeletos et al. \(2024\)](#): dividends are identical across households i , labor supply is intermediated by unions to obtain $L_{it} = L_t$, and income and taxes faced by households are equalized. Taking expectations and subsequently making use of the Fisher equation, we can then express the budget constraint in real terms as:

$$A_{i,t+1} = R_t (1 + \theta \mathbb{E}_t \Pi_{t+1}) \frac{1}{\omega} (A_{it} + Y_{it} - C_{it} - T_{it} + S_{it}), \quad (\text{D.16})$$

where R_t is the ex-ante real interest rate. This gives a simple Lagrangian resulting from the optimization problem:

This household problem yields a standard set of first-order conditions:

$$\{C_{it}\} : \quad C_{it}^{-\frac{1}{\sigma}} - \lambda_{it} \frac{R_t}{\omega} (1 + \theta \mathbb{E}_t \Pi_{t+1}) = 0, \quad (\text{D.17a})$$

$$\{L_{it}\} : \quad L_{it}^{\frac{1}{\varphi}} + \lambda_{it} \frac{R_t}{\omega} (1 + \theta \mathbb{E}_t \Pi_{t+1}) \frac{\partial Y_{it}}{\partial L_{it}} = 0, \quad (\text{D.17b})$$

$$\{A_{i,t+1}\} : \quad -\lambda_{it} + \beta \mathbb{E}_t \left[\frac{R_{t+1}}{\omega} (1 + \theta \mathbb{E}_t \Pi_{t+2}) \lambda_{i,t+1} \right] = 0, \quad (\text{D.17c})$$

The first-order conditions jointly yield a standard Euler equation for consumption:

³⁹The transfers are specified as $S_{it} = S^{new} = D^{SS} \geq 0$ and $S_{it} = S^{old} = -\frac{1-\omega}{\omega} D^{SS} \leq 0$, such that $(1 - \omega) S^{new} + \omega S^{old} = 0$.

$$C_{it}^{-\frac{1}{\sigma}} \left[\frac{R_t}{\omega} (1 + \theta \mathbb{E}_t \Pi_{t+1}) \right]^{-1} = \beta \mathbb{E}_t \left[C_{i,t+1}^{-\frac{1}{\sigma}} \right]. \quad (\text{D.18})$$

We linearize this expression through a standard first-order approximation, such that we obtain a linearized form of the Euler equation. Summarizing this equation across all households i , we arrive at the *aggregate* Euler equation, which will be at the centerpiece of our subsequent analysis:

$$\omega c_t = -\sigma(r_t + \theta \mathbb{E}_t \pi_{t+1}) + \mathbb{E}_t c_{t+1}. \quad (\text{D.19})$$

The intertemporal budget constraint

A crucial aspect of the analysis in [Angeletos et al. \(2024\)](#) is the *intertemporal budget constraint*, obtained through the per-period budget constraint jointly with the consumption Euler equation. With our return definition that accounts for the presence of inflation-indexed debt, that intertemporal consumption equation remains a generalization of the Permanent Income Hypothesis:

$$c_t = (1 - \beta\omega) \left(a_t + \mathbb{E}_t \sum_{s=0}^{\infty} (\beta\omega)^s (y_{t+s} - t_{t+s}) \right) - \beta \left(\sigma\omega - (1 - \beta\omega) \frac{A^{SS}}{Y^{SS}} \right) \mathbb{E}_t \left[\sum_{s=0}^{\infty} (\beta\omega)^s (r_{t+s} - \theta \pi_{t+1+s}) \right], \quad (\text{D.20})$$

where a_t captures net asset holdings of households and the additional inflation adjustment is the only novelty relative to [Angeletos et al. \(2024\)](#), capturing possible windfall income from surprise inflation due to holdings of inflation-indexed debt.

D.2 Standard NK elements

The supply side of the model is fully standard and follows any canonical New Keynesian model. In particular, the New Keynesian Phillips Curve arises as a consequence of standard Calvo pricing frictions included in a standard firm problem:

$$\pi_t = \kappa y_t + \beta \mathbb{E}_t [\pi_{t+1}], \quad (\text{D.21})$$

which can be iterated forward to express inflation as a function of current and future output gaps:

$$\pi_t = \kappa \sum_{k=0}^{\infty} \beta^k \mathbb{E}_t [y_{t+k}]. \quad (\text{D.22})$$

D.3 The Government Block

We begin our discussion of the government block by a brief derivation of the government budget constraint, which differs markedly relative to the version presented in [Angeletos et al. \(2024\)](#). The

simple per-period budget constraint of the government is defined as:

$$B_{t+1} = R_t^P (B_t - P_t T_t),$$

where $R_t^P \equiv I_t(1 + \theta\Pi_{t+1})$ captures the portfolio return that the government has to pay households. We therefore postulate that the government portfolio has a *fixed* share of inflation-indexed debt θ , with B_t capturing the total present value of all outstanding government bonds. Linearizing this constraint to express the evolution of the total debt portfolio d_{t+1} , we can express the government budget constraint as:

$$d_{t+1} = \frac{1}{\beta}(d_t - t_t) + \frac{D^{SS}}{Y^{SS}}r_t - \frac{D^{SS}}{Y^{SS}}((1 - \theta)\pi_{t+1} - \mathbb{E}_t\pi_{t+1}). \quad (\text{D.23})$$

The crucial novelty here is the adjustment of future inflation by $(1 - \theta)$. Intuitively, this captures the idea that inflation-indexed debt cannot be devalued through surprise inflation, as the face value of that part of the debt stock remains unchanged in present real terms irrespective of the rate of inflation. Therefore, the ability of governments to inflate away debt in real terms is constrained.

We furthermore retain the no-Ponzi condition of [Angeletos et al. \(2024\)](#), i.e., $\mathbb{E}_t \left[\lim_{T \rightarrow \infty} \beta^T d_{t+T} \right] = 0$. Starting off the steady-state where $x_{-1} = 0 \forall x \in \{d, t, r, y, \pi\}$, equation (D.23) pins down the initial change in the debt stock as a function of surprise inflation:

$$d_0 = -\frac{D^{SS}}{Y^{SS}}(1 - \theta)\pi_0.$$

To close the model, we specify appropriate fiscal and monetary policy rules.

The monetary policy rule deserves a brief special treatment as it is a point of departure from [Angeletos et al. \(2024\)](#). Following our derivation of equation (D.19), inflation-indexed debt can induce an intertemporal substitution effect through the Euler equation due to the possibility of windfall gains in the presence of surprise inflation. As we want to eliminate this effect and solely focus on the relevance of inflation-indexed debt through wealth effects induced by taxation, we postulate a monetary policy rule that absorbs the effect of inflation-indexed debt on the Euler equation:

$$r_t = \phi y_t - \theta \mathbb{E}_t \pi_{t+1}. \quad (\text{D.24})$$

This policy rule ensures that there is no distortion on the intertemporal aspects of household behavior induced by windfall gains from surprise inflation. Heuristically, central banks *care about the real interest rate that is relevant to households*. Denoting this policy-relevant interest rate by $\tilde{r}_t \equiv r_t + \theta \mathbb{E}_t \pi_{t+1}$, the monetary policy rule would simply be $\tilde{r}_t = \phi y_t$, nesting the model of [Angeletos et al. \(2024\)](#). This ensures that our subsequent analysis of both the monetary dominance case and the fiscal dominance case remain as closely aligned with [Angeletos et al. \(2024\)](#) as possible.

Given that the monetary rule also absorbs the effect of inflation-indexed debt on the government budget constraint in the case of surprise inflation, we re-introduce a dependence of taxation on the share of inflation-indexed debt, reflecting that the tax schedule must ensure that the quantity of taxes raised accounts for the possible cost incurred by the higher service cost of inflation-indexed debt in the case of higher rates of inflation. The fiscal rule otherwise remains the same as in [Angeletos et al. \(2024\)](#), such that we define for $\tau_d, \tau_y \in [0, 1)$:

$$t_t = -\varepsilon_t + \tau_d(d_t + \varepsilon_t) + \left(\tau_y y_t + \beta \frac{D^{SS}}{Y^{SS}} \theta \mathbb{E}_t \pi_{t+1} \right), \quad (\text{D.25})$$

where the last term reflects the novel adjustment of taxes to the expected costs incurred by inflation. Heuristically, governments *know* that surprise inflation can erode their budget balance (through higher face value payments on indexed debt), and they therefore adjust their taxation schedule to cover these expenses. Defining the quantity of taxes raised *net of* face value outlays for indexed debt as $\tilde{t}_t \equiv t_t - \beta \frac{D^{SS}}{Y^{SS}} \theta \mathbb{E}_t \pi_{t+1}$, we again nest the model of [Angeletos et al. \(2024\)](#). The quantity \tilde{t}_t reflects the discretionary tax revenue, i.e., the tax revenue available for the government once immediate obligations have been taken care of.

D.4 Equilibrium

The definition of the *competitive equilibrium* is standard and kept short on purpose..

Definition 2 *A competitive equilibrium is a stochastic path $\{c_t, y_t, \pi_t, a_t, d_t, t_t, r_t\}_{t=0}^\infty$ that satisfies the aggregate consumption function, the NKPC, market clearing ($c_t = y_t$ and $a_t = d_t$), the government's flow budget constraint and its no-Ponzi condition, as well as the fiscal and monetary policy rules.*

Our goal is to find that the proposition of [Angeletos et al. \(2024\)](#) claiming equivalence between fiscal dominance under RANK and monetary dominance under HANK in the limit point of the two policies does *not* hold. In our analysis of monetary dominance under HANK, we will therefore assume that $\phi = 0$ in the monetary policy rule.

D.5 Solving the model for flexible policy combinations

We are able to summarize equations (D.19), (D.21), and (D.23) (jointly with the monetary and fiscal rules (D.24) and (D.25)) in a first-order difference system, which will be the centerpiece of our dis-equivalence result:

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & -\theta \frac{D^{SS}}{Y^{SS}} & 1 \end{bmatrix} \mathbb{E}_t \begin{bmatrix} y_{t+1} \\ \pi_{t+1} \\ d_{t+1} \end{bmatrix} = \begin{bmatrix} \omega + \sigma\phi & 0 & 0 \\ -\frac{\kappa}{\beta} & \frac{1}{\beta} & 0 \\ \frac{D^{SS}}{Y^{SS}}\phi - \frac{\tau_y}{\beta} & 0 & \frac{1}{\beta}(1 - \tau_d) \end{bmatrix} \begin{bmatrix} y_t \\ \pi_t \\ d_t + \varepsilon_t \end{bmatrix}, \quad (\text{D.26})$$

which we can rewrite to:

$$\mathbb{E}_t \begin{bmatrix} y_{t+1} \\ \pi_{t+1} \\ d_{t+1} \end{bmatrix} = \begin{bmatrix} \omega + \phi\sigma & 0 & 0 \\ -\frac{\kappa}{\beta} & \frac{1}{\beta} & 0 \\ -\frac{\tau_y}{\beta} - \frac{D^{SS}}{Y^{SS}} \frac{\kappa\theta}{\beta} & \frac{D^{SS}}{Y^{SS}} \frac{\theta}{\beta} & \frac{1}{\beta}(1 - \tau_d) \end{bmatrix} \begin{bmatrix} y_t \\ \pi_t \\ d_t + \varepsilon_t \end{bmatrix}. \quad (\text{D.27})$$

The properties of the model depend on the eigenvalues of the previous matrix. Since the matrix is lower triangular, its eigenvalues are trivially given by the elements of its diagonal, such that the eigenvalues are given by:

$$\lambda_1 = \omega; \quad \lambda_2 = \frac{1}{\beta}; \quad \lambda_3 = \frac{1}{\beta}(1 - \tau_d). \quad (\text{D.28})$$

We trivially have two eigenvalues outside the unit circle for two forward-looking variables, satisfying the necessary conditions for a unique saddle-path equilibrium.

The stable eigenvalue will be $\lambda_1 = \omega$, which we will make explicit use of in the following. We also now restrict ourselves to the aforementioned *limit point between active fiscal and active monetary policy*: $\phi = 0, \tau_d = 0$. We do so to retain our focus on the 'equivalence result' between HANK and fiscal dominance that [Angeletos et al. \(2024\)](#) claim and that we intend to qualify. Let the eigenvector associated with the stable eigenvalue be denoted as $(\chi_1, \chi_2, 1)'$, such that we normalize the element pertaining to the state variable itself to 1. We can express the evolutions of all three endogenous variables in terms of the stable eigenvalue and its associated eigenvector:

$$y_t = \chi_1(d_t + \varepsilon_t); \quad \pi_t = \chi_2(d_t + \varepsilon_t); \quad \mathbb{E}_t d_{t+1} = \rho_d(d_t + \varepsilon_t). \quad (\text{D.29})$$

The three coefficients are given by the solution to the system $(A - \lambda_2 I)\chi = 0$, with $\chi_3 = 1$. That system is specified as:

$$\begin{bmatrix} \omega + \phi\sigma & 0 & 0 \\ -\frac{\kappa}{\beta} & \frac{1}{\beta} & 0 \\ -\frac{\tau_y}{\beta} - \frac{D^{SS}}{Y^{SS}} \frac{\kappa\theta}{\beta} & \frac{D^{SS}}{Y^{SS}} \frac{\theta}{\beta} & \frac{1}{\beta}(1 - \tau_d) \end{bmatrix} \begin{bmatrix} \chi_1 \\ \chi_2 \\ 1 \end{bmatrix} = \omega \begin{bmatrix} \chi_1 \\ \chi_2 \\ 1 \end{bmatrix}. \quad (\text{D.30})$$

This gives us the following two equations:

$$\begin{aligned} \chi_2 &= \frac{\kappa}{1 - \beta\omega} \chi_1 \\ \left[-\frac{D^{SS}}{Y^{SS}} \frac{\kappa\theta}{\beta} - \frac{\tau_y}{\beta} \right] \chi_1 + \frac{D^{SS}}{Y^{SS}} \frac{\theta}{\beta} \chi_2 + \frac{1}{\beta} &= 0 \end{aligned}$$

Thanks to the lower triangular structure of the matrix, we can easily solve the resulting system of equations and pin down χ_1 and χ_2 uniquely, yielding the sensitivity of inflation on impact in response to the fiscal shock ε_0 . We can pin down this sensitivity by solving the previous system of

equations, finding:

$$\pi_0^e \equiv \chi_2 = \frac{1 - \beta\omega}{\frac{D^{SS}}{Y^{SS}} \left[\frac{\kappa\theta + \tau_y}{\kappa} (1 - \beta\omega) - \theta \right]}. \quad (\text{D.31})$$

Note that without inflation-indexed debt ($\theta = 0$), we still retain the result that inflation is the same irrespective of the policy regime despite the presence of mortality risk in the HANK-Monetary Dominance world, since ω drops out of the above expression capturing impact inflation.

With inflation-indexed debt, however, we are able to summarize our main idea about the *dis-equivalence* of inflation in the limit point as part of the following proposition:

Proposition 4 *If either of the following sets of conditions hold:*

$$\frac{\kappa\theta + \tau_y}{\kappa} (1 - \beta\omega) - \theta > 0 \quad \& \quad \frac{\kappa\theta + \tau_y}{\kappa} (1 - \beta) - \theta > 0, \quad (\text{D.32})$$

$$\frac{\kappa\theta + \tau_y}{\kappa} (1 - \beta\omega) - \theta < 0 \quad \& \quad \frac{\kappa\theta + \tau_y}{\kappa} (1 - \beta) - \theta < 0, \quad (\text{D.33})$$

then impact inflation in response to an expansionary fiscal shock is higher in the policy limit point for the Fiscal Dominance-RANK economy relative to the Monetary Dominance-HANK economy.

Proof. Follows directly from the last equation provided. ■

E Additional evidence

E.1 The distribution of government debt holdings across households

Looking at publicly available microdata, a case for the relevance of the distribution of indexed debt in the household portfolio can be made. Please note that we leverage data on US households here, not on UK households, since we could not find publicly available microdata on UK households that explicitly capture holdings of inflation-indexed sovereign debt.

Figure E.1 plots the real (2017) Dollar value of nonindexed and indexed government debt holdings of households questioned in the US Survey of Consumer Finances (SCF), separated by income deciles.^{40,41} The left-hand panel of figure E.1 reflects the well-known left-skew of bond holdings of households in the income distribution, by which households at the upper end of the income distribution hold a significantly larger piece of sovereign bonds. The right-hand panel of figure E.1 reflects a less well-known observation: this left skew is *vastly* more pronounced for indexed

⁴⁰We chose income deciles due to their clear definition in the survey with a single question. Constructing individual wealth variables is possible with the survey data, albeit this is subject to individual choices about what to consider as household wealth. For most definitions of wealth, the results continue to hold qualitatively.

⁴¹Admittedly, using household survey responses to develop a profile of sovereign bond ownership is very far from perfect, since most sovereign bonds owned by households are only held indirectly through insurance companies and pension funds (and a vast share of sovereign bonds are held by Monetary Financial Institutions). Thus, finding the distribution of bonds held through such investment vehicles is of primary importance.

sovereign bonds (TIPS), with the top income decile holding almost 40% of all outstanding TIPS in the sample. This relative difference in the distribution of indexed bond holdings relative to nonindexed bond holdings is likely related to severe differences in the pricing of indexed and nonindexed bonds relative to the benchmark model above, which in turn would have significant influence on the determination of the price level.⁴²

Figure E.1: Distribution of indexed and non-indexed debt holdings across household income deciles, denoted in real (2017) USD. Data source: Survey of Consumer Finances (US); sample period: 2014-2019.

E.2 Further details on the Local Projections

To shed further light on the evidence presented in section 2.1, we here provide the result tables from the local projection on UK data presented in figure 3 and introduce additional evidence using US data with a similar exercise.

First, table E.1 summarizes the results given in figure 3, specifying the exact coefficients on the interaction effect of $\Delta\omega_t\varepsilon_t$ and the individual effects of the change in the indexed debt share $\Delta\omega_t$ and the identified fiscal shock ε_t on cumulative price level change from the pre-shock period -1 until the period specified above all columns.

While the share of indexed debt itself does not seem to impact medium-term inflation significantly, the interaction effect of the share of indexed debt with the identified fiscal shock follows the pattern given in figure 3.

To ensure that we are not solely picking up variation idiosyncratic to the UK, we utilize again the data provided by Mierzwa (2024) within an econometric specification adjacent to Cloyne et al. (2023), but here in relation to the series of US fiscal shocks identified therein. We leverage the number of identified fiscal shocks and estimate the same local projection specification (equation

⁴²Reaching the levels of skewness observed in the cross-sectional distribution of TIPS holdings is far from an easy feat. Thinking about this issue will be of utmost importance once the more urgent issues around the basic definition of the model are cleared.

Table E.2: Local Projection results for the US. Additional controls include past four-quarter lags of GDP growth, the Federal Funds Rate, real exchange rate growth, and year and recession dummies. Standard errors are robust to heteroskedasticity and autocorrelation (Newey-West correction).

⁴³We thereby utilize comparable time periods in our analysis of both the US and the UK.

Figure E.2: IRFs implied by a local projection in the style of equation (1). The control vector Z consists of the first four lags of the real GDP growth rate, the short-run nominal interest rate, the change in the weighted real exchange rate, and a same-period recession indicator. Standard errors are robust to heteroskedasticity and autocorrelation (Newey-West correction). Confidence intervals are provided at the 90% level. Sample length: 1980 Q1 - 2019 Q4.

The results here paint a supporting picture, as the interaction effect between the change in the share of inflation-indexed debt and the identified fiscal shock appears to be statistically significant in the medium-term again, even though the level of the effect is not as pronounced as in the UK.

Given the institutional arrangements in the US and the main estimation exercise in the paper, we use the US example to provide another piece of evidence by focusing *only* on fiscal policy surprises occurring in periods that can be considered as being supported by an *active fiscal policy* in the sense of [Leeper \(1991\)](#). To be precise, we leverage the Bayesian DSGE estimation of [Chen et al. \(2022\)](#), assigning the label of 'active fiscal policy' to periods in which the posterior probability of a fiscally dominant regime exceeds 0.8. This leaves us with 44% (33/75) of the original shock observations in the period 1980-2019. The resulting exercise with the reduced shock sample yields the results presented in table [E.3](#) and in figure [E.3](#).

Restricting our focus only on the sample periods to which we can assign a relatively high probability of a fiscally dominant regime, we can observe at first no significant response of cumulative inflation to the fiscal shock, followed by a gradually significant and positive response in the interaction effect of the indexed debt share and the identified fiscal shock in the medium-term, broadly in line with our previous results. The magnitude of the interaction effect more or less doubles relative to our previous analysis without the restriction on periods of active fiscal policy only.

E.3 Additional evidence on the nature of the September 2022 'Truss shock'

In this appendix, we provide additional selected evidence on the fiscal sustainability shock introduced through the announcement of the UK mini-budget, placing it in the context of general trends that were observed in the data at the same period, i.e., mainly in September and October 2022. For all analysis carried out in the following, a joint dataset of 'ticked' data (data available with the precision of seconds) as well as daily aggregates and prices updated only on a daily frequency of financial market variables, including market risk measures, expectations on future bond prices and interest rates, current bond prices and yields for nominal and real gilts, gilt futures, and

credit default swaps as a measure of default risk, have been used. The data comes from the Bank of England, the UK Treasury, and Bloomberg Financial Services.

The most crucial piece of evidence for the uncertainty and the sustainability concerns introduced by the UK's Fiscal Budget Plan comes perhaps from expected overnight interest rates. These are interest rates for overnight bank lending activities on financial markets, instrumented using swaps on overnight lending between the day at question and the day of the next monetary policy meeting. Normally, and as is the case for vast periods of the time, those swaps follow the prevailing nominal market rate closely, as any other rate would induce arbitrage by the possibility of a risk-free hedge using the current nominal interest rate. As figure E.4 shows, however, the turmoil introduced by the UK mini budget caused a remarkable wedge between the two rates for one week:

Figure E.4: The prevailing BoE Lending Rate and the Implied Overnight Interest Rate, derived by instrumenting overnight interest swaps from today to the expected next meeting of the BoE monetary policy committee meeting, both plotted over time. Data source: Bloomberg.

As can be inferred from the right-hand side panel for a period of almost three years, and on the left-hand side in more detail for our period of interest, the imputed overnight interest rate follows the BoE lending rate closely and is constant outside of meeting dates of the BoE Monetary Policy Committee, with the exception of very minor movements on random dates.

The period of the mini-budget, which commenced one day after a Monetary Policy Council (MPC) meeting (23rd of September and 22nd of September, respectively), induced movements in the expected overnight rates that were not observed at any other point in time - despite no BoE MPC meeting in sight⁴⁴, the expected overnight rates considerably shot up far beyond the BoE bank lending rate that was in place at the time, by up to 50 basis points. Such movements can be a po-

⁴⁴Notably, on the 27th of September, the BoE chief economist Huw Pill stated that the proposed UK government budget would require a "significant monetary response", indicating readiness on behalf of the BoE to adjust policy rates if necessary.

tential indicator for an array of different possibilities: it could be either that fiscal policy caused a shift in market expectations of monetary policy in the short-term, thus implying that monetary policy was considered to be 'reactive' to the fiscal policy announcement, or that the mini-budget was expected to have such detrimental consequences on inflation that the BoE was required to react immediately, or something completely different.

Correspondingly, and as can be inferred from figure E.5, prices of gilt futures dropped sharply during the period in which the UK mini-budget was expected to be put in place.

Figure E.5: Evolution of the weighted Gilt Future Index for futures due in Decemebr 2022, weighting gilt prices based on a normalized face value of 100, after adjusting for expected inflation. Data source: Bloomberg.

Since the expectations were that the mini-budget was supposed to be financed through a further issuance of gilts, the sharp decrease in the weighted index of gilt future prices can be considered a mechanical movement, caused by the expected sharp increase in the supply of gilts.

While changes in gilt prices and yields were one well-documented and highly discussed fact even in popular media, another frequently discussed aspect is the depreciation of the British Pound Sterling relative to the US Dollar. Instead of focusing on this well-documented and short-lived fact, however, we will provide evidence on the *relative* depreciation of the GBP over the Sterling Overnight Index Average (SONIA) by using the spread between swaps on GBP futures and SONIA futures, which concern *unsecured* transactions in the Sterling market on future dates.

Figure E.6 shows that the spread between GBP future and SONIA swaps shot up following the announcement of the mini-budget across all maturity dates. However, the yield curve of the spreads increased in *curvature* in its 'inverse-U' shape following the announcement of the mini budget, as is evidenced by the orange and red lines on the right-hand panel, which indicates particular concerns for the stability of the British Pound Sterling over the medium term.

Figure E.6: Yield Spreads between GBP future swaps and SONIA swaps on the overnight Sterling market. The left-hand panel plots spreads over time, while the right-hand panel plots yield curves on selected dates. Data source: Bloomberg.

While prices and yields show some crucial aspects of the market conditions at the time of the announced mini-budget, overall trade quantities can help us enrich the story by showcasing whether the overall *amount* of insurance products purchased markedly changed. One such insurance product are SONIA futures, as they provide the owner with a guaranteed overnight lending rate at a pre-defined point in the future. Since these instruments are centrally administered through the BoE, aggregate trade data are available and can be observed in figure E.7.

Figure E.7: Trade volumes in SONIA futures. The red line shows aggregate trade volumes (left axis), while the gray lines show the relative share conditional on the settlement date (right axis). Data source: Bloomberg/Bank of England.

The value of traded SONIA futures doubled shortly after the announcement of the mini-budget - since those futures provide liquidity insurance at a time when they become due, this can be interpreted as a reaction to heightened uncertainty about liquidity in bond markets. Following the initial sharp jump in the overall volume of trade in SONIA futures, the relative share of medium-term SONIA futures exceeded the trade share in short-term SONIA futures, as can be derived

from the two gray lines in figure E.7, i.e., investors shifted towards insuring themselves for longer periods of time at a period where the perceived will of the UK Treasury to push through with the mini-budget was still quite elevated, despite the initial backlash.

To provide evidence that this period coincides with overall elevated market risk, we provide a brief summary of perceived aggregate market risk in the UK, as we can observe an inversion of the relationship between aggregate risk and the time horizon considered.

Figure E.8: The uncertainty index over equity of the largest publicly traded British companies, aggregated and averaged over different horizons.

The mini-budget introduced an inversion of the market-perceived risk relative to the timespan considered: whereas in the periods before and after the mini-budget announcement market risk was perceived to be higher in the short-medium-term (180 days) than in the short-term (30 or 60 days), the opposite is the case during the short-lived fiscal crisis.

All these data points reinforce the idea that the ‘mini-budget’ announced by the UK Treasury in September 2022 was an unexpected fiscal measure that significantly subverted perceived fiscal sustainability, with wide-spread ramifications for expected real returns on government bonds, expected inflation and interest rates, and elevated risk levels.

FAQ: the ‘mini-budget shock’ episode

Why did markets reverse the uptick in inflation expectations initially?

- On September 26, around 4.00pm, Kwasi Kwarteng announced to publish a ‘medium-term fiscal plan’, which indicated more restraint in fiscal policy: ([Bloomberg](#))
- On September 28, a second shock to fiscal sustainability occurred: Moody’s explicitly deemed the mini-budget to put UK debt sustainability in danger, followed by a same-day upshoot of inflation expectations: ([Reuters](#))
- Likewise, on September 28, in a reversal of expectations caused by the September 26 statement, the Treasury explicitly rejected for the first time since the initial announcement any

idea of reneging on their budget shortfall, thereby re-affirming expectations about the fiscal policy measure actually being pushed through. See: (BBC). On the very same day, the Bank of England intervened in bond markets by re-starting long-dated government bond purchases, which, again, re-affirmed the idea that the Treasury will not back down as the Bank of England decided it must act despite no policy having been enacted at that point. This was announced at around 11.20am - see (X). Swap breakeven rates shot up by 60bps in the three hours after the statement made by the Bank of England.

Why were inflation swaps priced *much* higher in August 2022 compared to the dynamics occurring in September and October 2022?

- On August 17, 2022, the ONS released a report of CPI inflation being 10.1%, breaking the 10% barrier for the first time in 40 years, also beating the city forecast of 9.8% decisively (Bloomberg). This occurred alongside a significant depreciation of the Pound (FT). Likewise, implied interest rate raises corresponding to expectations of vastly more aggressive monetary tightening from that period onward alongside a yield curve inversion appeared around August 15 (FT).
- Implied one-year ahead inflation expectations peaked at around 8% in August. Note that this is still *vastly* below the forecasts released in August 2022 by major financial market actors: the Goldman Sachs forecast of one-year ahead inflation amounted to 14.8%, with a 'negative' scenario of 22.1% annual inflation for the UK implied in their August 2022 briefings (FT). Relative to that forecast, the change in inflation swaps implied in that policy uncertainty episode was relatively benign. This period of increased inflation expectations coincided also with record prices on natural gas spot markets in the UK.

F Bond market revaluations in response to narrative fiscal shocks in the UK

We leverage a novel dataset capturing the entire universe of UK sovereign debt (comprising of normal gilts, inflation-indexed gilts, treasury bonds, treasury strips, etc.) in the period from 2000 until 2010 to analyze bond revaluations in response to unanticipated fiscal spending shocks. The starting point of this analysis are the derivations from Cochrane (2023), and most notably the equilibrium valuation of government debt:

$$\frac{Q_t B_{t-1}}{P_t} = \mathbb{E}_t \sum_{j=0}^{\infty} \beta^j s_{t+j},$$

where Q_t refers to the price of government debt, B_{t-1} is the quantity of outstanding (marketable) sovereign debt, P_t is the price level, and s_{t+j} denotes the real government surplus at time $t + j$.

Accounting for the existence of long-term and inflation-indexed debt, this relationship changes to:

$$\frac{\sum_{j=0}^{\infty} q_t^{(t+j)} b_{t-1}^{(t+j)}}{P_{t-1}} + \frac{\sum_{j=0}^{\infty} Q_t^{(t+j)} B_{t-1}^{(t+j)}}{P_t} = \mathbb{E}_t \sum_{j=0}^{\infty} \beta^j s_{t+j}.$$

where superscripts denote the time of maturity of the bond at question and lowercase variables denote quantities and prices of inflation-indexed debt.⁴⁵ Note that we therefore define ‘indexed debt’ as a type of debt instrument whose principal payment is multiplied by the gross inflation rate between bond issuance and redemption, thereby mirroring the factual payment adjustment process commonplace in sovereign bond markets.

We now move this equation one period forward ($t \mapsto t+1$) and multiply/divide the latter element on the left-hand side by P_t :

$$\sum_{j=0}^{\infty} \frac{q_{t+1}^{(t+1+j)} b_t^{(t+1+j)}}{P_t} + \frac{\sum_{j=0}^{\infty} Q_{t+1}^{(t+1+j)} B_t^{(t+1+j)}}{P_t} \frac{P_t}{P_{t+1}} = \mathbb{E}_{t+1} \sum_{j=0}^{\infty} \beta^j s_{t+1+j}.$$

We now take first-differences of the expected values of the above relationship to capture surprise revaluations: $\Delta \mathbb{E}_{t+1} \equiv \mathbb{E}_{t+1} - \mathbb{E}_t$, based on objects that are not deterministic in t . This yields the following core equation:

$$\frac{\sum_{j=0}^{\infty} b_t^{(t+j)} \Delta \mathbb{E}_{t+1} (q_{t+1}^{(t+j)}) + \sum_{j=0}^{\infty} B_t^{(t+1+j)} \Delta \mathbb{E}_{t+1} \left(Q_{t+1}^{(t+1+j)} \frac{P_t}{P_{t+1}} \right)}{P_t} = \Delta \mathbb{E}_{t+1} \sum_{j=0}^{\infty} \beta^j s_{t+1+j}, \quad (\text{F.34})$$

which will be the main relationship pinning down our ‘net fiscal shock measure’.

What are the terms including ‘differenced expectations’, and can we recover them empirically? Consider the first term in the numerator of the fraction:

$$\Delta \mathbb{E}_{t+1} (q_{t+1}^{(t+j)}) = \underbrace{q_{t+1}^{(t+1+j)}}_{\text{Spot price after innovation}} - \underbrace{\mathbb{E}_t q_{t+1}^{(t+1+j)}}_{t \text{ to } t+1 \text{ forward price before innovation}} := \text{Forecast Error},$$

i.e., the surprise revaluation can be captured by means of differences between spot and forward prices. Note, however, that forward prices of bonds are hardly observable: while some forward contracts exist on bond ETFs, individual forwards can hardly be found, in particular for inflation-linked bonds that are comparatively illiquid.

The other innovation term that we must consider proves similarly cumbersome:

$$\Delta \mathbb{E}_{t+1} \left(Q_{t+1}^{(t+1+j)} \frac{P_t}{P_{t+1}} \right) = Q_{t+1}^{(t+j)} \frac{P_t}{P_{t+1}} - \mathbb{E}_t \left(Q_{t+1}^{(t+1+j)} \frac{P_t}{P_{t+1}} \right).$$

The first part is the ex post price of nominal debt adjusted for inflation, which is an easily retrievable

⁴⁵Derivations of similar relationships under the same complete-markets assumption are given in section 3.

object. The second part of the term equals the ex ante joint expectation over the nominal bond return and the inverse of inflation.⁴⁶

In our brief exercise, we aim to simplify the second term by considering sufficiently tight windows around fiscal announcement dates: 2 days before and after a shock, such that $\Delta t = 4$ days. In a span of four days, the price level is approximately unchanged, $\frac{P_t}{P_{t+1}} \approx 1$, thereby restricting our attention to the forecast errors in nominal and real bond prices.

The right-hand side stochastic term, $\Delta \mathbb{E}_{t+1} \sum_{j=0}^{\infty} \beta^j s_{t+1+j}$, is said to be the ‘shock’ in the narrow timeframe: we posit this to be some fiscal announcement, making the implicit assumption that any surprise to fiscal surpluses is fully self-contained and does not have further effects beyond the announced fiscal measure. The fiscal shocks considered here are the narrative shocks provided by [Cloyne \(2013\)](#), which limits the current sample size to the years 2000-2010. The construction of the shock series is modeled after the seminal paper of [Romer and Romer \(2010\)](#), and makes use of official documents released by UK legislators to ensure that only truly ‘exogenous’ discretionary tax changes are considered.

Data on bond prices and quantities are obtained from the Bank of England, the Treasury, Thompson Reuters, and the UK Government Securities Database maintained by [Cairns and Wilkie \(2023\)](#). The data were cross-checked across sources and corrected whenever errors were encountered, allowing us to avoid losing information on traded government bonds, as we need to paint the full picture of the universe of British sovereign debt.

Our final net shock measure consists then of the difference between the fiscal policy announcement given by [Cloyne \(2013\)](#) and the bond market innovation described above:

$$NetShock_{t+1} = \Delta \mathbb{E}_{t+1} \left[\sum_{j=0}^{\infty} \beta^j s_{t+1+j} - \sum_{t=0}^{\infty} b_t^{(t+j)} (q_{t+1}^{(t+j)}) - \frac{\sum_{j=0}^{\infty} B_t^{(t+1+j)} \left(Q_{t+1}^{(t+1+j)} \frac{P_t}{P_{t+1}} \right)}{P_t} \right]. \quad (F.35)$$

In words, this ‘net shock measure’ is a measure of the ‘action’ of the discretionary tax change (first term), adjusted for the ‘reaction’ of sovereign bond markets, i.e., the revaluation of outstanding debt (second term). Should our assumptions behind the derivation of this net shock measure be perfectly correct, we could expect the measure to be 0 at all times: if surpluses change, bond markets react by adjusting the real value of outstanding debt. If, instead, this measure has some variation, and it co-varies with the share of indexed debt outstanding, we may consider this evidence that inflation-indexed debt can be among the principal drivers informing fiscal theory when moving beyond our posited simplifying assumptions in deriving equation (F.35).⁴⁷

⁴⁶By the Fisher equation, this is the ex ante expected real return on holding nominal debt conditional on the risk premium.

⁴⁷A more in-depth analysis of sovereign income and spending, including a detailed analysis of corresponding bond revaluations and yields borne on sovereign debt, is provided by [Chen et al. \(2022\)](#).

Figure F.1: Estimated Kernel density of the net shock measure described by equation (F.35) for the United Kingdom, 2000-2010.

Figure F.1 plots the density of this shock measure, showing that it is quite centered around zero, but not exactly symmetric. This may either be related to an issue in the definition of the shock series, problems with the assumption of the expectations hypothesis being a reasonable approximation to bond market behavior in such narrow time frames,⁴⁸ or it may be related to market incompleteness and possible differences in insurance premia between the two types of bonds.

We will now argue that the last case might bear some relevance with the help of the following simple estimation exercise:

$$NetShock_t = \alpha + \beta \frac{\sum_{j=0}^{\infty} B_t^{*(t+j)}}{\sum_{j=0}^{\infty} b_t^{(t+j)} + B_t^{(t+j)}} + \Gamma_t X_t + \varepsilon_t, \quad (F.36)$$

i.e., we project the net shock measure on the share of inflation-indexed debt and a set of controls, which can include a year fixed effect to account for long-run changes in spending behavior as well as a recession indicator. The results of this exercise are given by the following figure F.2 and the corresponding regression table.

Despite the low variation in the share of indexed government debt in the United Kingdom from 2000 to 2010, the results showcase a possible correlation between the share of indexed debt and the unexplained variation in UK bond market valuations of government debt. As mentioned above, those results must be taken with caution, but this provides a stepping stone informing our analysis of the relevance of inflation-indexed debt in relation to surprise fiscal shocks, and how the two jointly influence real and nominal economic outcomes.

⁴⁸The expectations hypothesis was used to derive the otherwise unobservable forward prices of all traded bonds.

	<i>Dependent variable: Shock Measure</i>
